Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag 1981: 123–63.

Data Sheet

PDS* and PDS II (Polydioxanone) Sterile Monofilament Synthetic Absorbable Suture

---

Presentation

PDS and PDS II (Polydioxanone) Monofilament Synthetic Absorbable Sutures are prepared from the polyester poly (p-dioxanone). The empirical molecular formula of the polymer is $(C_4H_6O_3)n$. PDS (Polydioxanone) sutures are coloured by adding D & C Blue No. 6 during polymerisation. PDS II (Polydioxanone) sutures are coloured by adding D & C Violet No. 2. PDS II sutures may also be manufactured undyed (clear). PDS and PDS II (Polydioxanone) are available attached to stainless steel needles of various types and sizes, and are sterilised by ethylene oxide gas.

PDS and PDS II (Polydioxanone) sutures are relatively inert, non-antigenic, non-pyrogenic and elicit only a mild tissue reaction during absorption.

Action: Two important characteristics describe the in-vivo behaviour of absorbable sutures. The first of these is tensile strength retention and the second absorption rate or loss of mass. The general mechanism by which in-vivo degradation of polydioxanone occurs is hydrolysis.

Data obtained from implantation studies in rats show the following absorption profile:

14 days post implantation –
 70% strength remaining
28 days post implantation –
 50% strength remaining
56 days post implantation –
 14% strength remaining

This indicates a significantly longer period of wound support than previously available with an absorbable suture.

The absorption or loss of mass is minimal until about the 90th post implantation day and is essentially complete within 180 days.

Uses

PDS and PDS II (Polydioxanone) monofilament sutures are intended for use where an absorbable suture or ligature is indicated. They may have particular application where longer wound support is required. See strength retention data above.

Dosage and Administration

By implantation.

Contra-indications, Warnings, etc.

These sutures, being absorbable, should not be used where extended approximation of tissues under stress is required or in conjunction with prosthetic devices e.g. heart valves or synthetic grafts.

The safety and effectiveness of PDS and PDS II (Polydioxanone) sutures in neural and cardiac tissue have not been established.

As with all monofilament synthetic sutures, care should be taken to ensure proper knot security.

Conjunctival, cuticular and vaginal epithelium sutures could cause localised irritation if left in place for longer than 10 days. Superficial placement of subcuticular sutures may also be associated with erythema and reaction during the course of absorption.

Pharmaceutical Precautions

Recommended storage conditions are below 25°C, away from moisture and direct heat. Shelf life is 5 years, the expiry date is shown on each pack. Do not re-sterilise the contents of the pack. Unused product from opened packs should be discarded.

As with all sutures, care should be taken to avoid damage when handling. Avoid the crushing or crimping application of surgical instruments such as needle holders and forceps to the strand, except when grasping the free end of the suture during an instrument tie.

Legal Category

Not applicable.

Package Quantities

PDS is available in various lengths in gauge sizes Metric 0.2 to 0.4 (10/0 to 8/0). PDS II is available in various lengths in gauges sizes Metric 0.5 to 5.0 (7/0 to 2). The sutures are packaged in sealed aluminium foil packs and peel apart overwrap pouches. The sales unit is a film wrapped box containing 12 or 24 packs.

Further Information

No suture related adverse reactions were reported during clinical trials, although a number of minor reactions were classified as being of unknown cause.

SPLANCHNIC ISCHEMIA AND MULTIPLE ORGAN FAILURE

Edited by Adrian Marston, Gregory B Bulkley, Richard Fiddian-Green and Ulf H Haglund

This book is the first authoritative text on a problem of major importance in intensive care medicine.

- Chapters by leading international authorities including scientists, surgeons, microbiologists and immunobiologists.
- Brings together all the elements that lead to circulatory disruption, septicemic shock and multiple organ failure.

£65 net July 1989

International Medical Course

Peripheral vascular disease

29 May – 1 June 1990, London

This course is designed for surgeons and others with an interest in surgical aspects of peripheral vascular disease. The course will cover all aspects of arterial, venous and lymphatic disease including pathology, diagnosis and treatment. The following topics will be discussed: pathology of atherosclerosis; basic principles of vascular surgery; non-invasive investigation of vascular disease; radiobiological investigation and radiological intervention in vascular disease; arterial operations; venous disease; venous operations; lymphatic disease and operations.

The emphasis will be on practical procedures with workshops and video presentations and there will be opportunities for brief presentations of unusual or problem cases by course participants.

The course will be directed by **Professor N L Browse,** United Medical and Dental Schools of Guy's and St Thomas' Hospitals, University of London also Consultant Surgeon, St Thomas' Hospital, London and **Mr K G Burnand,** Reader, Department of Surgery, St Thomas' Hospital Medical School.

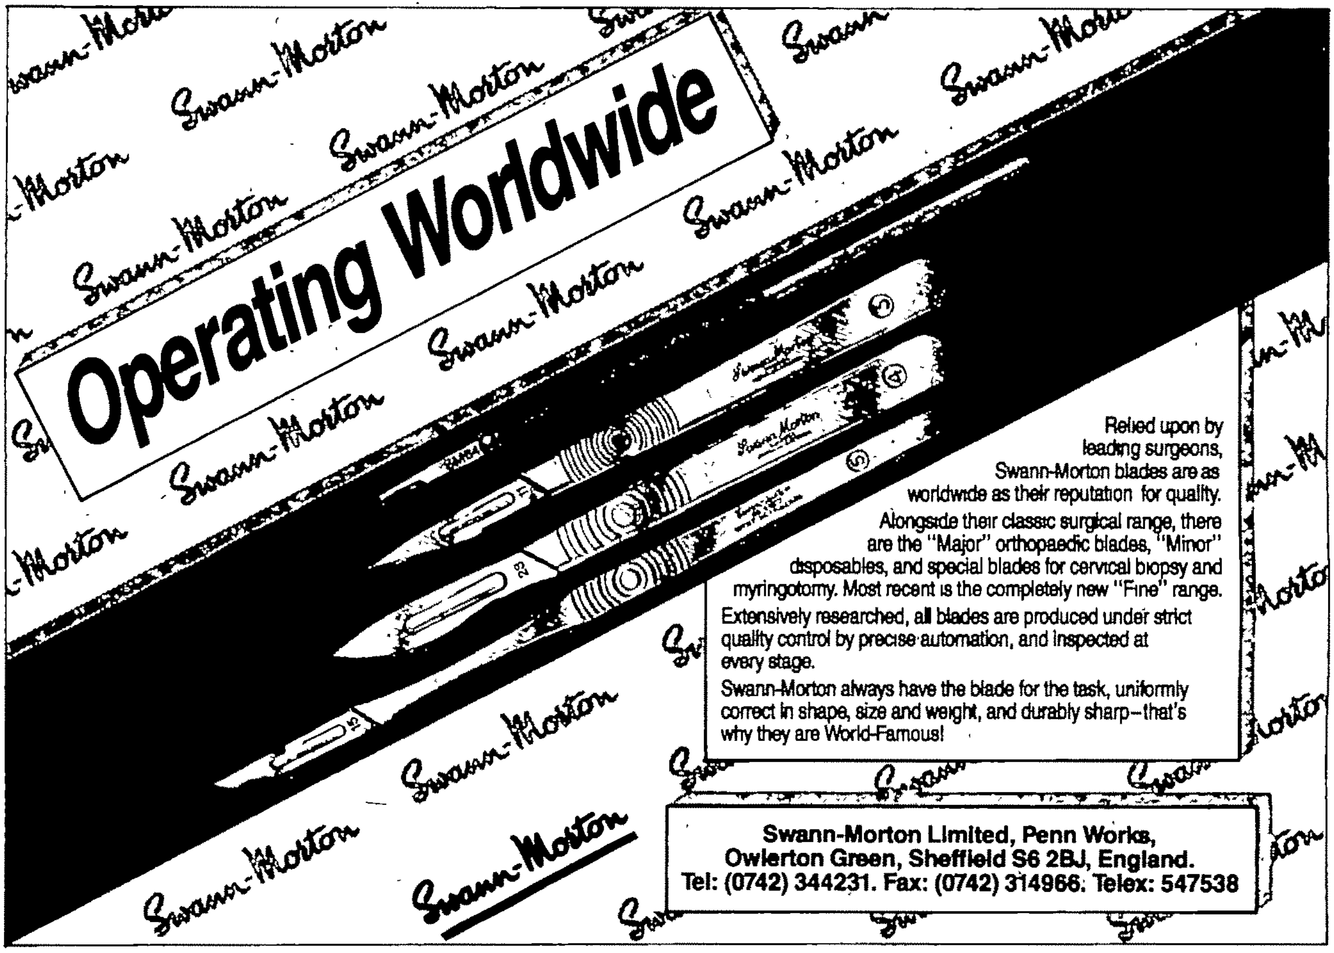
There are vacancies for 30 participants.

Course fee: £435; accommodation fee: £145; total fee; £580.

The course will be held at St Thomas' Hospital Medical School Postgraduate Centre and course members will be accommodated at a nearby hotel.

The British Council

Further information and application forms are available from British Council Representatives overseas or from Courses Department, The British Council, 65 Davies Street, London W1Y 2AA



Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality.

Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp–that's why they are World-Famous!

NEW FROM BUTTERWORTHS

Positioning the Surgical Patient

J. M. Anderton, FFARCS Consultant Anaesthetist, Manchester Royal Infirmary **R. I. Keen,** FFARCS Consultant Anaesthetist, Manchester Royal Infirmary **R. Neave,** FMAA Medical Artist, University of Manchester

★ Explains clearly the 'how' and 'why' of patient positioning. ★ Superb illustrations demonstrate all important positioning techniques. ★ Indispensable to anyone working in the operating theatre.

The correct positioning of the surgical patient is of vital importance to a successful outcome. Each type of operation demands that the patient be placed in a particular way, but for each position there are associated problems and risks. This is the first short textbook to explain the 'how' and 'why' of patient positioning, and it does so in a clear and comprehensive manner.

The authors use a carefully integrated mixture of text and line illustrations to describe the purpose of the main surgical positions. For each, they then cover in detail the associated anatomical hazards; the specific techniques required to achieve the correct position – illustrated with action sequences drawn from actual operative situations; and conclude with variants of the basic positions. A final chapter on respiratory and circulatory aspects highlights the physiological implications for the patient of the different positions.

Although precise details of practice vary from hospital to hospital, the authors concentrate on the principles rather than the minutiae. The result is a textbook which should have broad appeal to anyone with operative surgical responsibilities. This includes surgical and anaesthetic staff, who have the primary task of selection and general implementation of patient position, as well as nurses and operating department assistants who play an indispensable role in its detailed execution.

CONTENTS The supine position • The lithotomy position • The lateral position • The prone position • The sitting position • The transfer of patients and recovery room practice • Specialized positions • Physiological effects of posture in the anaesthetised patient • Index *March 1988 128 pages 246 x 189 mm Softcover 156 line illustrations 0 407 012206 £12 95*

Barrett's oesophagus

Nearly 40 years have passed since Norman Barrett described in this Journal the condition of *Chronic peptic ulcer of the oesophagus and 'oesophagitis'*[1]. He initially thought that this was a congenital short oesophagus with an intrathoracic stomach, but Allison and Johnstone pointed out that the organ lined by 'gastric' mucous membrane was oesophagus[2]. It is now generally accepted that the columnar-lined oesophagus is the result of long-continued gastro-oesophageal reflux which has denuded the squamous epithelium, allowing the acid resistant gastric-type epithelium to replace it from below, upwards. Two experimental models have shown that the replacement can result from an upwards 'creeping substitution' from the gastric cardia[3] or can result from cells from oesophageal gland ducts[4]. It has also been described following caustic burns and after chemotherapy.

Barrett's oesophagus is not an uncommon condition in children, but is more prevalent in late middle age. In some series a columnar-lined oesophagus is found in 10 per cent of patients with gastro-oesophageal reflux. Gastro-oesophageal reflux appears to be predominantly a western disease and is uncommon in negroid and oriental populations. The condition should be expected when there is a history of long-continued reflux, but in 10–20 per cent of patients there may not be a classical history of reflux. The epithelium is notably unstable, and approximately 60 per cent of patients present with a stricture, 20 per cent with ulceration, 18 per cent with bleeding and 13 per cent with adenocarcinoma. The risk of developing adenocarcinoma, however, has been shown on surveillance studies to be low. Six reports of surveillance results revealed only 11 cases of adenocarcinoma from a total of 456 patients followed for 3–20 years. A population survey in progress has shown that only about one in 20 cases of Barrett's oesophagus in the general population has been diagnosed[5]. Radiologically, a columnar-lined oesophagus should be suspected when there is a high stricture, a long stricture or ulceration in the body of the oesophagus. Endoscopy is essential to make the diagnosis which is confirmed histologically.

Of great significance is the fact that a severe motility disorder accompanies the columnar lining. Whether the motility disorder predates the columnar lining or whether it results from reflux damage is still debated. However, Zaninotto *et al.*[6] have suggested that there is progressive deterioration of function when comparisons are made between normal individuals and patients with uncomplicated reflux or stricture or columnar-lined oesophagus. In Barrett's oesophagus, there was the greatest prevalence of a mechanically defective lower oesophageal sphincter, interrupted swallow responses, and simultaneous contractions in the oesophageal body. The loss of propagating waves is probably due to neural damage, and whether this is the direct result of reflux has yet to be proved. This damage appears to be irreversible because it is not corrected by medical or surgical therapy.

Physician gastroenterologists and surgeons have opposing views regarding the management of the columnar-lined oesophagus. The efficacy of medical treatment has increased remarkably since the advent of the H_2-receptor blocking drugs, omeprazole, and prokinetic agents, and there are now reports of more successful control for up to 6 years. These patients must, however, continue therapy for life and their life-span may be restricted by the fact that there is no available medical treatment to reverse a mechanically defective sphincter. Of 18 patients in the author's series who were treated medically on standard doses of H_2-receptor blocking drugs and prokinetic agents, progression of the columnar lining was documented in 14 of these patients during a surveillance period of up to 6 years. Recent reports from other centres also suggest a failure of H_2-receptor blockade and double doses are advocated.

Surgery, at best, will effectively prevent reflux in some 90 per cent of patients followed for 10 years. There are no reports of progression of the columnar segment, reulceration or stricturing following surgery. There is however no proof that either medical or surgical treatment will prevent adenocarcinoma, and further data are required to resolve this important issue. There are also no comparative prospective studies on the effect of medical or surgical treatment on subsequent life-style. Repeated

0007-1323/89/100995–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

prospective monitoring of oesophageal function in patients with a columnar-lined oesophagus who are treated medically or surgically is necessary to test the efficacy of such treatments. If there is progressive irreversible deterioration of motility owing to gastro-oesophageal reflux, there would be a firm case for earlier surgery in Barrett's oesophagus. Physicians and surgeons should therefore enter into prospective studies and surveillance of all patients with gastro-oesophageal reflux in an effort to establish whether their own respective treatments influence progression.

There is also evidence to support the concept that the complications seen in the columnar-lined oesophagus are related to 'alkaline' reflux. In complicated Barrett's oesophagus there is an increased exposure to an alkaline pH (Reference 7). Whether the irritant agent in the alkaline reflux is bile or pancreatic juice is also not defined. There is as yet no effective medical treatment for alkaline reflux. The need for surveillance of the columnar-lined oesophagus has also been questioned in the light of the low return, in terms of cancer detection, in four series[8], but the concensus view is to continue these studies until more definite guidance can be given. Biopsy evidence of severe dysplasia has indicated the high probability of an associated invasive cancer and the need for resection, but in the two studies reported there were only ten cases with dysplasia of this severity[9,10]. Nine of these patients underwent oesophageal resection and invasive cancer was present in six of the specimens examined. The Organisation for International Studies of Diseases of the Oesophagus (OESO) has recently launched an international collaborative study in an effort to answer some of these questions[11] and the study should be supported and encouraged.

Malignant melanoma: a plague of our times

Malignant melanoma, the most malignant of skin cancers, has doubled in incidence in the last 10 years, and fourfold increases in a decade have been reported in some patient groups[1]. World-wide statistics demonstrate an average rise in incidence of 7 per cent a year. To put this in perspective, a rising incidence of this nature in Scandinavia would lead to malignant melanoma becoming more common than breast cancer by the year 2000[2]. Although many factors are at play in this phenomenon, there seems little doubt that changes in today's society are largely responsible. Increasing exposure to high intensity sunlight is probably the most telling factor and it seems likely that this has rendered a susceptible fair-skinned, so-called Celtic, population at a much higher risk of developing malignant melanoma than before. However, it should be noted that other factors are important. In Scotland, of 951 melanoma patients, over 50 per cent had never left the UK, even for a brief holiday in continental Europe[3].

The most important prognostic factor in primary cutaneous melanoma is tumour (Breslow) thickness[4] and it is encouraging to learn from the Australian experience and from recent educational programmes in the UK that at least some of the morbidity and mortality may be prevented by excising the primary lesion at an earlier, thinner stage[5]. However, despite the ever-enlarging world experience in the treatment of melanoma patients it is noteworthy that controversy rages over just about every other aspect of their management.

Traditional dogma held that the primary lesion should be excised with a healthy 5-cm margin of normal skin. Because of the anatomical distribution of melanomas such a policy frequently necessitated the use of skin grafts and often produced a very unsightly result. Fortunately such teaching has been called into question in recent times. Concern over the radical excision of primary lesions arose from the fact that despite apparently curative removal of the lesion a significant percentage of patients returned with locoregional deposits. Many of the issues concerning the management of the primary lesion were addressed in a leading article in this Journal in 1986[6]. Currently, the consensus seems to suggest that a 3-cm margin of excision is adequate. A recent study even suggests that a mere 1 cm would be sufficient for those lesions less than 2 mm in thickness[7]. It would also appear to be quite safe to obtain any donor skin graft from the ipsilateral limb.

As the regional lymph nodes are the most common site for melanoma metastases considerable attention has been focused on their management. Surgical excision offers the only effective cure and is the best method of locoregional disease control Surgeons are divided between those who advocate excision of only clinically demonstrable metastatic nodes and those who support a policy of mandatory prophylactic lymph node dissection. The latter policy is based on fear of the presence of occult or microscopic metastases. Traditionally, this operation was reserved for extremity melanomas with lymph node drainage to a single group of nodes. However, some workers have even suggested that some trunk primaries are amenable to lymph node dissection as long as no more than two nodal groups are draining the primary lesion. The opposing viewpoint to this rather aggressive stance is the one that holds that the available evidence is increasingly pointing to malignant melanoma being a systemic disease, not unlike breast cancer. Nonetheless, the controversy regarding lymph node dissection has raged for over two decades and centres on two main points of discussion. Firstly, is it possible to identify the subgroup of patients who are at high risk of developing nodal metastases? Secondly, when should the node dissection be performed? Lack of good scientific data has dogged this question from the outset. Indeed, it still remains that only two prospective randomized trials have addressed the value of elective lymph node dissection in stage I melanoma patients[8,9]. Neither of these studies has proved the case satisfactorily. A rational consensus view has been expressed by Balch[10] who suggests that 'physicians will have to ... make their best judgements about the management of regional lymph nodes in an individual patient setting'. Certainly, in view of the worrying level of morbidity associated with lymph node dissection, it would seem unreasonable at this time to subject all stage I patients to this procedure outside the setting of a clinical trial.

Following the successful use of regional isolated perfusion with melphalan for the treatment of unresectable melanoma, the question logically arose about its use in an adjuvant setting for stage I melanoma of the extremity. Can it be used to eliminate microscopic metastatic cells not removed by primary surgery, and does this improve survival? Over the last decade large numbers of patients have been entered into a series

0007-1323/89/100997-02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

of trials addressing these questions and to date hard evidence confirming the efficacy of this technique is lacking[11,12]. Differences in subgroup randomization and distribution in the published studies have rendered interpretation of the data difficult. In addition, in the appraisal of an adjuvant treatment, the added risks and burden to the patient are important factors that must be weighed against the expected gains. To an even greater extent than is the case with elective lymph node dissection, the role of isolated perfusion is in doubt. Toxicity is significant, as is functional limb impairment, limb loss and even death. It would seem reasonable to suggest at this time that this technique should be withheld for those patients with multiple extremity recurrences who cannot easily be treated by surgical excision.

Until such time as public education campaigns have a significant impact on the long-term pick-up of early primary melanoma lesions it seems likely that a considerable number of patients will present for treatment with advanced disease. Attempts to address this subgroup of patients will remain urgent in view of their frequently young age. Regimens of traditional chemotherapeutic agents have consistently proved disappointing with response rates lower than 20 per cent and should probably be avoided because of high levels of toxicity. Immunotherapy has always seemed an attractive proposition owing to the known immunogenic nature of melanomas. It is perhaps in this field more than any other that advances have been made in the last 5 years. The use of interferon and decarbazine suggested the possibility that improved response rates might be attainable. However, it was not until the pioneering work of Rosenberg from the US National Institute of Health began to become available that real progress was demonstrable[13]. Increased response rates are now being achieved utilizing various regimens of interleukin 2, interferon, cyclophosphamide and lymphokine activated killer cells. More recently the combination of reinfused autologous tumour infiltrating lymphocytes and high-dose interleukin 2 has achieved partial responses in some 60 per cent of cases. Although these therapies have yet to be subjected to the rigour of randomized clinical trials, the available results do suggest that immunotherapy represents a genuine advance. Perhaps the advances achieved in the management of disseminated melanoma may provide a clue to a more logical adjuvant therapy for stage I disease.

Sad though it may seem, the practical management of patients with malignant melanoma may have turned full circle. The primary lesion should be excised with a reasonably clear margin, and grafted if necessary. The regional lymph nodes should probably be left alone unless they are clinically involved when block dissection seems to offer the best chance of control. Isolated limb perfusion almost certainly should not be employed outside the current clinical trials. Finally, the management of advanced disease may be about to turn some sort of a corner in the next 5 years, and it may best be approached immunologically. Through a better understanding of adoptive immunotherapy in these cases we may see light at the end of the tunnel in our management of 'earlier disease'.

Damage sustained by an ischaemic kidney is reduced by cooling the organ. For this reason kidneys are rapidly cooled during the retrieval operation and preserved at low temperature before implantation. When the kidney is removed from cold storage for implantation into the recipient it gradually rewarms (second warm ischaemic time) and a prolonged second warm ischaemic time has been shown to be a cause of acute tubular necrosis following transplantation. The temperature rise in a kidney during implantation has been poorly investigated and little work to minimize that rise has been carried out. This study investigates, in an animal model, the changes that occur in the core temperature of kidneys during the second warm ischaemic time. A jacket has been designed which greatly reduces the rate of kidney rewarming during simulated operative conditions. Kidneys unprotected by the test system showed a rapid rise in temperature from a mean of 1°C to a mean of 20°C after 45 min, compared with those kidneys placed in the protective jacket in which the temperature rose to a mean of only 8°C in the same time. The jacket is not bulky and is simple to use. Maintaining a low kidney core temperature during the second warm ischaemic time will reduce injury to the kidney and should be part of routine clinical practice.

Keywords: Renal transplantation

Cadaveric kidneys sustain damage during retrieval from the donor, during storage, and during implantation into the recipient. However, such damage may be reduced by lowering the temperature of the kidney during each of these events[1]. Renal oxygen consumption falls exponentially with temperature and this is associated with a 1·5–2-fold decrease in enzyme activity for every 10°C drop in temperature[2]. The three major phases of transplantation when renal injury may occur are:

1. *Retrieval:* kidneys are cooled rapidly in the cadaver donor during the retrieval process using a technique known as '*in situ* perfusion'. The aorta is cannulated and cold flushing of the kidneys performed immediately circulation ceases in the donor. This reduces the ischaemic damage during this period, termed the first warm ischaemic time
2. *Preservation:* the second phase is that of preservation during which time the recipient is selected and preparation made for the transplantation operation. It was shown in the 1960s that kidneys could be safely preserved by ice cooling or continuous hypothermic perfusion[3,4]. Both of these systems rely on maintaining the kidney at a low temperature and therefore this phase is called the cold ischaemic time
3. *Implantation:* the final phase of the transplantation procedure is when the kidney is removed from storage and implanted into the recipient. During the time taken to anastomose the renal vein and artery to the recipient vessels the kidney gradually warms and yet is still without a blood supply. This time interval is termed the second warm ischaemic time

The net result of the ischaemic damage which occurs during these three phases may produce acute tubular necrosis in the donor kidney, causing delay in the onset of renal function. Any delayed function has important implications for the transplant recipient who will need dialysis, who will require to stay in hospital longer and in whom the diagnosis of rejection will be more difficult. There is evidence that delay in the onset of graft function adversely affects long term graft survival[5,6]. When cyclosporin A is used that evidence is particularly strong, with one study showing 75 per cent graft survival at 1 year when the onset of graft function is delayed, compared with 91 per cent when immediate function occurs[7]. Recent reports examining the causes of delayed graft function have shown that a long second warm ischaemic time leads to a significantly increased risk of delayed function[8,9]. As it is known that warm ischaemia will severely damage a kidney in 60 min[10] and that

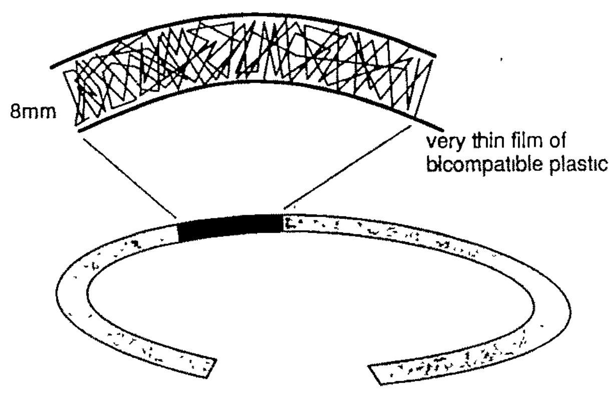

Figure 1 *Illustration of present design jacket*

kidneys can be stored for up to 72 h when cold, there are obvious advantages in preventing rewarming of the kidney before it is connected to the circulation of the recipient. Until now only basic attempts have been made to keep the kidney cool during the transplant operation, usually by wrapping it in gauze soaked with cold saline.

The aims of the study were to investigate the temperature changes that occur in the kidney during the vascular anastomosis phase of the transplant operation in an animal model, and to design a system that would keep the temperature of the cooled kidney below 10°C for 40 min. A realistic system would need to be simple to use, non-bulky, allow easy access to the renal vessels for anastomosis and be either disposable or easy to sterilize.

Materials and methods

An animal model was designed to reproduce the operative conditions that exist during the second warm ischaemic time of the transplant operation. Pig kidneys from the abattoir were used. The pigs were killed by stunning and exsanguination and their kidneys were removed within 20 min of death and cooled. Two methods of initial cooling were used. The kidneys were either infused via the renal artery with cold perfusate solution and then placed in ice, or placed in ice without prior infusion. The core temperature of the kidneys on removal from cold storage was the same regardless of which cooling method was used and comparisons were always made between paired kidneys which were cooled in the same way. All kidneys were placed in plastic bags and stored in crushed ice in the same way as human kidneys are preserved in the UK.

The two kidneys were removed from cold storage in an operating theatre. One kidney was wrapped in gauze soaked in ice-cold saline. The second kidney was placed in the system under test. If there was a size discrepancy between the two kidneys, the larger one was used as the 'test' kidney. Thereafter, the kidneys were subjected to exactly the same conditions. The energy striking the experimental surface was controlled as follows. First, the kidneys were supported on a thin film of plastic over a water bath, the temperature of which was maintained at 30°C. Secondly, energy from the operating theatre light was measured using a lux meter and maintained at 30 klx by adjusting the height and focus of the light. This figure represents a power dissipation of 142·5 mW/cm^2.

Temperature was measured using a minithermocouple probe attached to a digital meter data logger (Grant Instruments, Cambridge, UK). This enabled accurate temperature measurement to be made every minute for the first 5 min after removal from cold storage. Readings were then taken every 5 min up to 45 min. This time was chosen as it represents the upper limit of the second warm ischaemic time in clinical renal transplantation on our unit. Temperature measurements were recorded at four sites: (1) water bath, (2) air temperature at experimental surface, (3) core of kidney (control), and (4) core of kidney (test).

Cooling systems tested

Several systems were tested and discarded for a variety of reasons: continuous flow of cold saline or gas around the kidney (these methods were cumbersome and difficult to use); an envelope of ice around the kidney (this was bulky and difficult to handle); aluminium foil (this was much more pliable and moulded to the desired shape well, however, it did not perform well in laboratory bench tests because of accelerated heating in certain circumstances).

Consideration of the basic physics of the problem suggested that the thermal conductivity of the material in use was the major factor which could be altered without increasing the bulk of the 'jacket'. An easily available substance with a low thermal conductivity is air. It was from this simple idea that the prototype was developed and improved to become the system tested (*Figure 1*). It consists of two thin films of a biocompatible plastic, which sandwich a weave of a similar plastic containing air trapped among the fibres of the weave. The jacket thus formed measures 8–10 mm in thickness and can be used for small or large kidneys. It is closed around the hilum of the kidney by a simple draw cord which allows the renal vessels to protrude.

Results

Throughout all experiments, the water bath temperature was maintained in the range 27–33°C and the air temperature in the operative field was recorded as 28–38°C. Mean results over 12 paired experiments for these two parameters are listed in *Table 1*. On removal from the preservation system, the core temperature of all kidneys ($n = 24$) was 0–1°C (mean 0·6°C). In 12 paired experiments, the kidneys that were allowed to warm sustained a predictable rise in temperature of 2°C (mean 1·9°C) per 5 min interval, from 5–45 min. The core temperature of these kidneys was always above 10°C by 20 min. The final temperature at 45 min was 16–25°C (mean 19·6°C). The core temperature of the paired kidneys placed in a cooling jacket rose at a mean of 0·9°C per 5 min interval in the 5–45 min period. The mean temperature at 45 min was 8·0°C and was always below 10°C at this time. These figures are listed in *Table 1* and illustrated in *Figure 2*.

Table 1 *Mean temperatures recorded in 12 paired animal model experiments*

	Temperature (°C)			
Time (min)	Water	Air	Core kidney (normal)	Core kidney (test)
0	32·2	31·0	0·6	0·6
1	32·0	31·1	1·1	0·7
2	31·4	31·2	1·7	0·8
3	31·0	30·8	2·4	0·9

Discussion

This study has demonstrated that the core temperature of kidneys stored before transplantation is between 0 and 1°C, a fact not always appreciated by transplant surgeons. It is important to place the kidney in fluid during ice preservation as failure to do so may allow freezing of the parenchymal tissue with resulting intracellular crystal formation and cell damage. Indeed, recent evidence suggests that such low temperatures may not be ideal for kidney preservation[11].

A number of studies have demonstrated that keeping a kidney cool during a period of ischaemia improves ultimate function[12,13]. It is the practice of some surgeons to pour aliquots of cold saline intermittently on to the kidney during the second warm ischaemic time. Nevertheless, in a separate experiment this was shown not to lower the core temperature and it had minimal effect on slowing the rate of temperature rise. To obtain a satisfactory cooling effect, cold saline had to be run over the kidney in a continuous stream.

Other methods of keeping the kidney cool[14] (using jackets) during the second warm ischaemic time have not met with acceptance owing to the bulk or complexity of such devices, which make the performance of the vascular anastomoses more difficult. The cooling system employed must not only keep the kidney cool but also must not handicap the surgeon. A jacket, such as the one described, is non-bulky, simple to use, disposable, and allows access to renal vasculature while still maintaining the kidney at a low temperature. This jacket is being commercially developed and when a suitable sterile form has been made it will be tested during clinical transplantation.

In the early days of transplantation it was recognized that ischaemic injury must be minimized. This objective has been largely achieved during the retrieval operation and during a limited preservation period. Slowing the rate of the temperature rise during the second warm ischaemic time will further reduce ischaemic injury and should, therefore, become part of clinical practice.

Professor P. J. Morris, University of Oxford, John Radcliffe Hospital, Headington, Oxford OX3 9DU, UK

Skin cancer was found in 31 of 598 patients transplanted in Oxford. No cases occurred during the first 3 years after transplantation but the prevalence rose after 12 years to 18·2 per cent. The main risk factors predisposing to skin cancer were the time after transplantation and male sex. Comparison with data from other centres suggests that exposure to ultraviolet light is a major aetiological factor in the speed of development of skin cancer. As the incidence of new cases rose progressively with time in our patients, it would seem that skin cancer is likely to become a major clinical problem as more patients enjoy prolonged survival after renal transplantation. Preventative and screening measures should be taken by transplant units both in the UK and in other countries with similar temperate climates.

Keywords: Skin cancer, renal transplantation

Dermatological problems such as warts and solar keratosis occur frequently in renal transplant recipients with an incidence of up to 90 per cent in one large series[1]. Similarly, the incidence of cancer of all types is increased, being especially marked for lymphomas, cervical cancer and skin cancers[2,3]. However, the majority of these cancers appear on the skin and are predominantly squamous cell carcinomas[4,5].

The increased risk of development of skin cancer in renal transplant recipients has been described in populations with heavy sunlight exposure, such as those of Australia[5–7] and South Africa[8]. However, the incidence of skin malignancy in more temperate European climates is less well defined and has generally been thought to be less of a problem than in those closer to the equator. We have studied skin cancer in our centre to assess the incidence of this complication.

Patients and methods

From January 1975 to May 1988, 598 patients received 707 renal transplants in Oxford: 649 from cadaver donors and 58 from living related donors. In addition, 21 foreign patients received living related transplants, but they have been followed up abroad and are not included in this analysis. In the period of this study the form of immunosuppression has changed several times From 1975 to 1978 azathioprine and high dose steroids were used[9], and from 1978 azathioprine with low dose steroids were used[10]. In 1979 cyclosporin was introduced in trials with conventional therapy[11], followed by triple therapy with cyclosporin, azathioprine and steroids in 1985[12].

All transplant recipients are followed regularly in the outpatient department and the skin is systematically examined. All suspicious skin lesions are biopsied and, in addition, patients with known skin problems, either malignant or premalignant, are seen regularly by a dermatologist (V.A.V.) in a clinic devoted to dermatological surveillance in transplant recipients. A register of all histologically proved malignancies has been prospectively compiled In addition to squamous cell carcinoma, basal cell carcinoma and malignant melanoma, the register has included all patients with carcinoma *in situ* (Bowen's disease) and keratoacanthoma. The patients with keratoacanthoma were included as histological differentiation from squamous cell carcinoma may be difficult[13,14]. In our series all patients with this diagnosis also had a frank cutaneous malignancy. Dermatological conditions such as solar keratosis and viral warts are not considered in this study. Statistical analyses were performed using Student's t test, the χ^2 test and linear regression analysis as appropriate.

Results

Types, sites and number of tumours

Thirty-one of 598 patients (5 per cent) developed 98 skin cancers. Eight (26 per cent) of these patients had single lesions, eight (26 per cent) had multiple lesions of the same histological type and 15 (48 per cent) had multiple lesions of more than one histological type (*Tables 1* and *2*). *Figure 1* shows the anatomical distribution of these cancers, which were most commonly found on sun exposed areas of the body. *Figure 2* shows the prevalence of affected patients in the transplant population and *Figure 3* shows the incidence of new cases per year in previously unaffected patients. The data in *Figures 2* and *3* are for patients with functioning first grafts only.

Table 1 *Histological types of skin cancer in 16 patients with lesions of one histological type only*

Type of cancer	Total number of patients affected	Number of patients with single lesions	Number of patients with multiple lesions (number per patient)	Total number of lesions
Bowen's disease (carcinoma *in situ*)	1	1	0	1
Squamous cell cancer	11	6	5 (2, 2, 2, 5, 7)	24
Basal cell cancer	3	2	1 (2)	4
Malignant melanoma	1	1	0	1
Total	16	10	6	30

Table 2 *Combinations of skin cancer in the 15 patients with multiple malignancies of different histological types*

Type of skin cancer	Number of patients (number of lesions per patient)	Total number of lesions
Bowen's + SCC	3 (2, 2, 3)	7
SCC + BCC	1 (3)	3
SCC + KA	3 (3, 5, 9)	17
SCC + KA + BCC	1 (5)	5
BCC + SCC + Bowen's	1 (3)	3
Bowen's + SCC + KA	3 (3, 4, 11)	18
Bowen's + BCC + KA	1 (5)	5
Bowen's + SCC + KA + BCC	2 (5, 5)	10
Total	15	68

SCC, squamous cell cancer, BCC, basal cell cancer; KA, keratoacanthoma

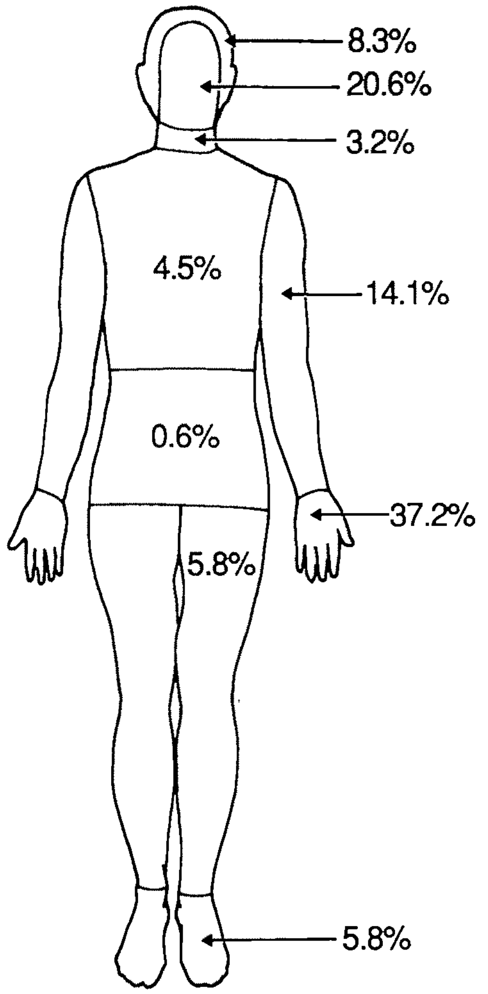

Figure 1 *Distribution in the body of 98 skin cancers*

Age and sex

The mean age at the time of transplantation of the patients who subsequently developed skin cancers was 41·9 years (range 11–67 years). This was not statistically different from the mean age at the time of transplantation of all other recipients (mean age 39·2 years, range 7–67 years). Skin cancers developed in five (2·3 per cent) of the 222 female renal transplant recipients and in 26 (7·9 per cent) of the 370 male recipients. The higher incidence in male recipients is statistically significant ($P < 0{\cdot}05$).

Type of underlying renal disease

There was no difference in the incidence of the various conditions causing end-stage renal failure in the patients with or without skin cancer.

Type of immunosuppression

The incidence of skin cancer was not related to the type of maintenance immunosuppression used. Three patients with skin cancer received cyclosporin together with prednisolone and/or azathioprine, and 28 received azathioprine and steroids. There was no statistical difference in the incidence of skin cancer in patients given azathioprine with high or low dose steroids. No patient given antithymocyte globulin has subsequently developed a skin cancer although the follow-up is less than 3 years .

Time to detection of cancer

The mean time from transplantation to diagnosis of the first skin cancer was 84·6 months (range 43–132 months). In the 18 patients who developed a second cancer, the mean(s.d.) interval between detection of the first and second cancers was 15(12) months. In the 11 patients who developed a third cancer, the mean(s.d.) detection interval between the second and third cancer was 11(9) months. This tendency toward a shorter detection interval with subsequent cancers was not statistically significant but the numbers in our series are small. *Figure 4* shows data from five patients, all with four or more malignancies. If it is assumed that after the second new cancer these tumours developed at a constant rate, linear regression analysis demonstrates a mean(s.d.) growth/detection rate of 0·11(0·11) cancers per month, which represents a mean rate of development of 8·9 months per cancer in these patients.

Treatment and outcome

All patients were treated by excision of the tumour and other suspicious areas. One patient was also treated with local radiotherapy after excision of a squamous cell cancer. The single patient with malignant melanoma had wide local excision and a split skin graft. There have been no regional or distant metastases to date from any of the skin tumours. One patient who developed axillary lymphadenopathy following excision of a forearm squamous cell carcinoma was subjected to axillary lymph node dissection, but histological examination showed no evidence of tumour. In one patient, widespread perianal squamous dysplasia and carcinoma *in situ* were treated by wide excision and withdrawal of immunosuppression. His graft failed, and he remains well on maintenance haemodialysis, although there are still some residual skin changes which are felt to preclude retransplantation with the need for reinstitution

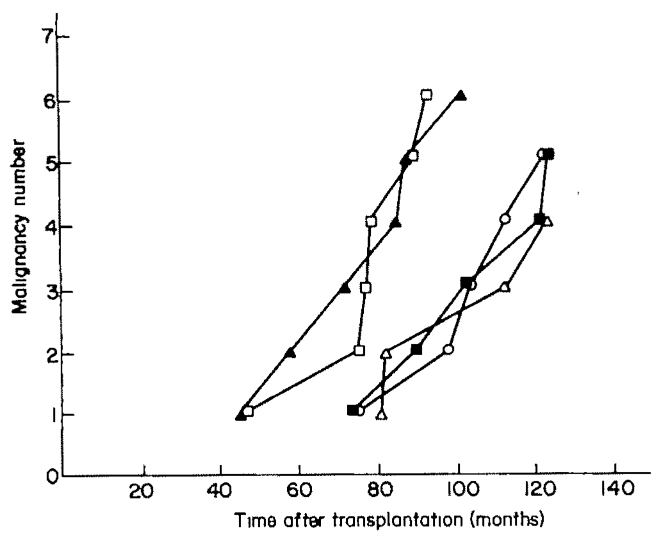

Figure 4 *The occurrence of skin cancers with time in five patients who have experienced multiple cancers Linear regression analysis shows a mean interval of 8 9 months between the occurrence of each new cancer*

of immunosuppression. One patient who experienced multiple squamous cell carcinomas of the skin developed a poorly differentiated non-Hodgkin's lymphoma and has died from this. Another patient has died from an unrelated condition.

Discussion

The aetiology of skin cancers in renal transplant recipients is multifactorial and includes exposure to ultraviolet light, immunosuppressive drug treatment and viral infection. Genetically determined skin type and colour are also important, but the discussion will be confined to Caucasian patients, as they form the principal risk group.

The most important risk factor predisposing to skin cancer was time from transplantation and hence the duration of immunosuppressive therapy, and this was irrespective of the age of the patient at transplantation. Thus, cancer should be suspected in all transplant patients with suspicious skin lesions whatever their age, although in our patients we did not see any cancers until more than 3 years after they had first received a renal transplant.

The relative risk of developing a skin cancer in patients with a renal transplant compared with the general population increased with time after transplantation to about 100-fold. The incidence of squamous cell cancer in the general population in the UK has been calculated at 7·5 cases per 100 000 per year[15]. The incidence of new cases of skin cancers in previously unaffected transplant patients rose to over 3500 per 100 000 population in year 8 after transplantation, with a trend to a further increase with time (*Figure 3*). By comparison, the state of Queensland in Australia has the highest incidence of skin cancer in the world, with 211 cases per 100 000 of the general population per year, and the relative risk of developing skin cancer during year 9 after transplantation is also about 100 times that of the general population[5] As these calculations do not take age-related risk into consideration, the true relative risk may be underestimated.

Ultraviolet light causes many of the changes that lead to skin cancer. As has been noted in previous reports on renal transplantation, the majority of malignancies in our patients developed in areas of the body exposed to the sun (*Figure 1*). However, we were unable to relate the incidence of cancer in our patients to outdoor occupations, in contrast to another study from the UK where such a relationship was established after prospectively interviewing the patients[16]

Exposure to ultraviolet light is also related to the geographical latitude of individual transplant centres. It is difficult to compare the incidence and prevalence of skin cancer in different centres around the world. Most reports do not show the prevalence related to time after transplantation, and do not report the incidence of new cases in their patients as we have done in this analysis Comparable data are available from Brisbane, Australia[5], and their results are compared with ours in *Figure 2*. The prevalence of skin cancer is not only higher in Brisbane than in Oxford, but the cancers appear sooner after transplantation. The prevalence of skin cancer in other UK centres is probably similar to that in Oxford[16–18]. In Götenburg, Sweden, there is a striking similarity to our results, with no cases in the first 3 years after transplantation, and a rise in prevalence to about 20 per cent by 12 years after transplantation[19].

Although there are little data on the prevalence of skin cancer with time after transplantation, several centres report the mean time from transplantation to detection[5,14,20]. These data are biased to only a minor extent by variations in duration of follow-up in different centres. The speed of development of skin cancer is related to the latitude of each transplant centre, again confirming the importance of exposure to ultraviolet light (*Table 3*).

The details of the mechanisms whereby ultraviolet light leads to skin cancer are unclear. The DNA of keratinocytes may be damaged by sunlight[21] and such potentially oncogenic changes may be potentiated by photo-oxidative effects of the metabolites of azathioprine[22,23]. It has recently been shown that, in an *in vitro* model, glucocorticoids together with human papilloma virus and the human *ras* oncogene may lead to the oncogenic transformation of otherwise normal cells[24]. Viral infection may play an important part in the development of these cancers and human papilloma virus has been identified in a number of cases of squamous cell carcinoma[25–28]. A causative role for this virus in the development of skin cancer in transplant patients is one possible explanation for the observation that the incidence of squamous cell cancer is higher than that of basal cell cancer, in this series as in previous reports[2,6,7]. This is in contrast to the general population, where basal cell cancer is more common than squamous cell cancer.

Although treatment with immunosuppressive drugs does predispose to skin cancer[3,6], there is no evidence from clinical trials to suggest that any particular immunosuppressive drug is a dominant risk factor. Cyclosporin has not been in use long enough to draw any firm conclusions about whether it confers a greater or lesser risk than other drugs. However, there has been concern about the future possible development of skin cancer with cyclosporin due to the development of photosensitization in sunlight and a generalized increase in squamous epithelial growth[29]. In this series, the follow-up time is too short to assess the relative risk of cyclosporin treatment. However, one study has shown no difference between the incidence of skin cancers in patients randomized to receive either cyclosporin or prednisolone and azathioprine during a 5-year follow-up period, but the number of affected patients in the study was very small[30].

Male patients receiving transplants were more likely to develop skin cancer after transplantation than female patients in this study, as also noted previously[6,8]. The reason for this is unclear, although differences in sun exposure, hormonal

Table 3 *Mean time from transplantation to detection of cancer related to the geographical latitude of various transplant centres*

Transplant centre	Latitude (degrees)	Mean time from transplant to detection of skin cancer (months)
Oxford	52	84 6
Wisconsin[14]	45	78
Denver, Colorado[20]	40	58
Brisbane, Australia[5]	34	32 6

responses or skin types might all be relevant. In one report it has been suggested that the development of some skin cancers may be related to recipient human leucocyte antigen (HLA) type. Basal cell carcinoma was associated with a higher than expected frequency of HLA-A1 and lower than expected frequency of HLA-B12 (K.I. Welsh, E. Higgins, A.M. Tidmos *et al.*, unpublished results). However, in our patients there was no such relationship.

Other series have noted that skin cancers in transplant patients may be unusually aggressive, with deaths and nodal metastases[2,6,7]. These aggressive cancers have been recorded in Australia and New Zealand and it may be that the skin cancers in temperate Europe are less of a threat.

Prevention of skin cancers is an important feature in routine follow-up in many transplant centres, although it is unclear how much difference active preventative measures actually make. We advise our patients to keep out of the sun as far as possible and to wear long sleeved shirts and brimmed hats when in the sun. Skin creams that provide total block to ultraviolet light are also recommended. Early detection of cancer makes surgical excision easier and reduces the risk of tumour spread, so that our patients are advised to check their own skin in addition to the routine checks at outpatient follow-up visits. The use of systemic retinoids appears to be very effective in patients with solar keratoses and warts, but may be less effective in those with multiple squamous cell cancers[31]. Further studies of the efficacy and safety of retinoids are indicated, but they may become important therapeutic and preventative agents in some patients.

In conclusion, although skin cancer in renal transplant recipients in the UK is less aggressive and occurs later after transplantation than in countries closer to the equator, it is still a significant cause of morbidity. As the risk of developing skin cancer seems to be primarily related to the duration of immunosuppression, it is likely to become a more significant problem in the future as more patients survive for longer periods with a functioning graft.

Death and injury due to terrorist bombings continue to exercise civilian and military surgeons alike. In this paper 828 servicemen killed and injured by explosions in Northern Ireland have been studied, using data stored in the Hostile Action Casualty System (HACS). Because of the nature of the conflict in Northern Ireland, the magnitude of each explosion and the distance of the victims from it are quite accurately known. The overpressure (blast loading) to which the victim was exposed can be estimated from the information on the HACS forms and standard tables, giving overpressures for a given charge at a known distance. Using the HACS data, the numbers of injuries due to overpressure (primary blast injury), missiles energized by the blast (secondary injury), displacement of the victim by the blast wind (tertiary injury) and flash burn can be determined. Of the 828 servicemen involved in explosions, 216 were killed, most of them before any treatment could be instituted. Of the servicemen in the survey, 90 per cent were wearing body armour. Although body armour affords considerable protection from secondary missiles, it is unlikely to reduce the number of deaths due to primary blast injury.

Keywords: Explosions, blast injury, Hostile Action Casualty System

Terrorist bombings are a major cause of death and severe injury in both civilian and military practice. The patterns of injury caused by blast are complex. In this paper, the injuries caused by explosions in 828 servicemen serving in Northern Ireland between October 1970 and May 1984 have been studied, using data stored in the Hostile Action Casualty System (HACS)[1]. Because of the nature of the troubles in Northern Ireland, the magnitude of each explosion and the distance of the victims from it are quite accurately known. Using this information the approximate overpressure to which the victim was exposed can be estimated, and so the number and type of injuries related to the severity of the blast loading can be determined: namely, blast lung injury, displacement of the victim by the blast wind, flash burn injuries and impact of missiles energized by the blast. The significance of these findings in the light of recent research into the nature of blast injury is discussed.

Methods

The HACS was set up by Lt Col. Owen-Smith in the late 1970s, while he was Professor of Military Surgery, to fulfil a need for accurate analysis of wounds sustained in action, their treatment and the end result[1]. Because of the nature of the troubles in Northern Ireland it is possible to obtain forensic data on each incident. Thus the magnitude of an individual explosion in each incident can be ascertained. A standard form (the HACS coding sheet) is completed for each injured serviceman. The relevant information for size of explosive device and distance from the casualty is shown in *Table 1*. The various combinations of weight of explosive and distance are given as a serial number for computer coding.

The stored information pertaining to those servicemen killed or injured by explosions between October 1970 and May 1984 was studied with particular reference to the size of the charge and the distance of the victim from it.

Using standard data (examples of which are given in *Figure 1*), each of serials 30–44 (*Table 1*) could be allocated to one of four groups denoting the severity of blast loading (*Table 2*). During the period under review, commercial rather than military explosive was used and the grouping is based on the blast produced by commercial blasting gelignite with a detonation velocity of about 4000 m/s (rather less than that of trinitrotoluene). Those in group 1 would have been exposed to the lowest overpressure (predicted to be only sufficient to cause ruptured tympanic membranes), whilst those in group 4 would have been exposed to the highest overpressure (predicted to be sufficient in a high proportion to cause severe, probably fatal primary lung injury).

Results

Between October 1970 and May 1984, explosions accounted for the deaths of 216 servicemen, 31 of whom were totally disrupted. The survivors were classified as having had major, moderate or minor injuries. There were 92 major, 89 moderate and 431 minor injuries. *Table 3* shows the distribution of degree of injury within the four groups described in *Table 2*. The majority (90 per cent) of the servicemen killed or injured by explosions in this period were wearing body armour. Less than 20 per cent wore helmets.

Modes of death

Table 4 shows modes of death related to the estimated blast injury sustained. Apart from those who were totally disrupted by the blast, the remainder fell into four distinct subgroups. The first and largest subgroup of fatalities had mixed patterns of injuries including head, chest and secondary missile injuries. The significance of each component in any fatality is uncertain, although in group 4 'blast lung' (see below) was present in all cases in which forensic reports were available.

In groups 1, 2 and 3 there was a second subgroup in which head injury alone was an important cause of death. There is a third subgroup of fatalities in group 4 with head and chest injury (in the form of blast lung) alone. The fourth distinct subgroup, 'severe chest injury alone', is that in group 4. Servicemen in this subgroup died with no serious external injury. Their mode of death is discussed below.

Of the 216 fatalities, 174 were dead before any assistance could be rendered. Twelve died in hospital, of overwhelming injuries, whilst resuscitation was being commenced, and seven died on the operating table. Twenty-three patients died after initial resuscitation: of these, seven died peroperatively (three of severe head injuries with massive intracerebral haemorrhage, one of uncontrollable intra-abdominal and intrathoracic bleeding, two of blast lung in the form of massive haemoptysis, and one of the effects of a major traumatic amputation).

Sixteen survived their initial operations. Eight died of severe head injuries, four of whom had no other injuries. Seven survived their operations but died of blast lung, although whether this could be ascribed solely to blast-induced pulmonary contusion or was aggravated or indeed caused by sepsis or prolonged hypovolaemic shock is by no means clear. These factors probably contributed to the death of the patient with the traumatic amputation (*Table 5*).

Survivors requiring laparotomy and/or ventilation

There were only five patients who fell into this category and all had been in vehicles involved in accidents as a result of an explosion. One was in group 2 and required suture of stomach and liver alone. Two were in group 4; both required ventilation following laparotomy, and one required elevation of a skull fracture. Two survivors from group 3 (severe blast loading) with no external injuries had lung damage severe enough to warrant ventilation.

Incidence of perforated eardrum in survivors of blast

There were 288 survivors of explosions who had perforated eardrums. This occurred in about 50 per cent of the survivors

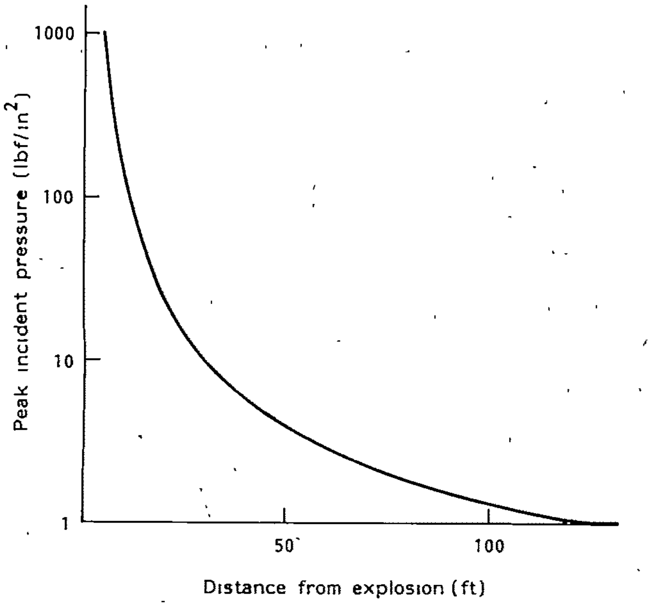

Figure 1 *Standard curve showing the decay in incident pressure of the blast wave against distance for a 50 lb charge of trinitrotoluene. The overpressure is inversely proportional to the cube of the distance from the explosion for a given charge. (Non-SI units are used to correspond to the Hostile Action Casualty System (1 lbf/in^2 ≈ 6·9 kPa) forms.)*

Table 2 *Victim groups according to blast loading*

Group	Overpressure (lbf/in^2)*	Blast loading
1	<20	Minor: maximum overpressure sustained sufficient to cause ruptured tympanic membrane
2	20–50	Moderate higher overpressure than group 1, but probably insufficient to cause primary lung damage in a significant number of casualties
3	50–80	Severe: sufficient overpressure to cause primary lung damage in a significant proportion of casualties
4	>80	Very severe: sufficient overpressure to cause severe primary lung damage with a significant incidence of death

* 1 lbf/in^2 ≈ 6·9 kPa

Table 5 *Postoperative deaths following blast injury*

Group	Injuries	Operation	Cause of death
1	Multiple secondary missile wounds	Wound toilet	ARDS
	Head, chest, abdomen	Splenectomy, nephrectomy	Head injury
2	Head, chest, abdomen	Thoracotomy, splenectomy, liver suture	Head injury
	Chest, abdomen	Cardiac suture, splenectomy, liver suture	ARDS
	Head, chest, abdomen	Laparotomy	Head injury
3	Traumatic amputation	Wound toilet	?
	Head, chest, traumatic amputation	Wound toilet	Head injury
	Head, chest, abdomen	Cardiac suture, splenectomy	ARDS
4	Traumatic amputation, chest, abdomen	Wound toilet, liver suture	ARDS
	Chest, abdomen	Splenectomy	ARDS
	Traumatic amputation, chest, abdomen	Wound toilet, liver suture	ARDS
	Traumatic amputation, chest, abdomen	Wound toilet, liver suture	ARDS

Where ARDS (adult respiratory distress syndrome) has been cited as a cause of death, it cannot be stated whether this was due to the primary effects of the blast itself or other causes such as shock, sepsis, etc. A further four died solely of head injury

Table 6 *Numbers of blast victims and percentage with ruptured tympanic membranes related to estimated blast loading*

	Group			
	1	2	3	4
Fatalities ($n=216$)	5 (0)	28 (60)	38 (78)	145 (96)
Survivors ($n=612$)	250 (47)	107 (52)	162 (49)	93 (38)
All blast victims ($n=828$)	255 (48)	135 (60)	200 (55)	238 (83)

Values in parentheses are percentages

in each of groups 1–3 (*Table 6*). The percentage of survivors in group 4 with perforated eardrums was rather lower, although when those who died of blast injury are included (all of whom had perforated eardrums) there is a much higher incidence in group 4. None of the five who survived laparotomy and/or ventilation had perforated eardrums. In all, 137 sustained permanent hearing loss.

Head injuries

One hundred and fifty two servicemen who died from blast injury had head injury as a contributory factor. Of these, 25 were killed by head injury alone, 44 by a combination of head injury and blast lung alone, 24 by head injury, blast lung and intra-abdominal injury, and 56 had additional secondary missile injuries. Five patients with severe head injury alone survived long enough to be ventilated, but only one of these recovered

Of 113 with less severe head injuries, seven were left with some form of central nervous system defect attributable to the injury.

Limb injuries

In all, 298 servicemen sustained limb injuries, 106 of whom sustained lower limb injuries, 89 upper limb injuries, and in 103 both the upper and lower limbs were injured. Of these, 45 had residual lower limb problems, sufficient to require late amputation in two instances, 21 had residual upper limb problems, and two had late amputation.

The majority of these injuries were caused by secondary missiles. When traumatic amputation caused by the blast wind occurred, survival was limited (*Table 7*).

Burns

Only 31 servicemen sustained burns as part of their injury. Of these, three in group 4 died (of other injuries). In the remainder, burns were superficial and healed without complication.

Table 7 *Traumatic amputation following explosion in 52 servicemen*

Discussion

An explosion is essentially a rapidly expanding sphere of high-pressure, high-temperature gaseous products, resulting from the rapid chemical decomposition of the explosive substance. The sphere is known as the blast wave and reaches its maximum overpressure virtually instantaneously. The wavefront reduces in pressure as an inverse cube of the distance from the explosion (*Figure 1*). The wavefront propagates through the air, and mass movement of air displaced by the explosive products causes the blast wind that follows an explosion, which is known as the dynamic pressure. When the blast wave interacts with an object in its path important phenomena occur. Part of the incident wave is reflected and reinforces the oncoming wavefront and may increase the local overpressure up to eightfold. A stress (pressure) wave may couple into the object. If it reaches an interface between areas of differing densities, part is reflected and part continues on. Pressure differentials (stresses) occur at the interface between media of differing density. These stresses are most marked at air–fluid interfaces, so that in the body the lung is most readily affected. The pressure differentials across alveolar–capillary interfaces may disrupt the barrier, resulting in haemorrhagic contamination of alveoli (blast lung).

Secondary injuries are caused by fragments of casing, glass and masonry energized by the explosion. The blast wind accelerates bodies in its path, causing injuries of varying severity, including traumatic amputation (so-called tertiary injury). Flash burns and local fires will occur due to the intense local heat of the explosion, although this soon dissipates with time and distance from the explosion. In this survey, most of the burns were of the 'flash' type, as the amounts of explosive used in terrorist bombs during this period were for the most part relatively small (see below). Clothing generally provides adequate protection from flash, and burns tended to be superficial and healed without complication.

From the clinical point of view, the important effects of the blast wave itself, in the absence of significant penetrating wounds, are ruptured tympanic membrane, primary lung damage, traumatic amputation and death. The four groups described are broadly based on the minimum overpressure required to produce these phenomena (*Table 2*). It has been stated that exposure to significant blast is unlikely if the victim has intact ear drums[2], and only 38 per cent of survivors in group 4 were recorded as having ruptured ear drums (*Table 6*). There are three possible explanations.

Firstly, although the threshold for rupture of the exposed tympanic membrane may be as little as 2 kPa, the loading on the tympanic membrane depends critically on the orientation of the head towards the incident wave. Secondly, although the victims in this group were close to a blast of some magnitude, there are many factors, such as position of furniture, pillars, cars and other victims, that could reduce the blast loading on the body within confined spaces[3]. However, loadings may increase owing to reinforcement of reflected waves. This accounts for severe blast injury in victims at what would normally be a safe distance from the explosion. Thirdly, the presence of ruptured tympanic membrane is probably under-reported, particularly in the severely injured where it may escape attention. In the forensic reports obtained, ruptured tympanic membrane had been reported in all those exposed to severe blast.

It has been generally accepted for many years that pulmonary contusion occurs as a result of compression of the lungs between rib cage and thoracic spine. Gross deformation of the rib cage can certainly be seen on high-speed cinephotography, but may not be primarily responsible for the lung injury. Cooper and Taylor[4] have identified three other mechanisms by which blast may cause internal injury. These involve the propagation of waves through the body in the form of stress waves, shock waves and shear waves.

Stress waves are longitudinal pressure waves similar to sound waves. They travel through tissue at roughly the same speed as sound waves but have a much higher amplitude. Shock waves are a special form of stress wave having a very high pressure and causing effectively an instantaneous wavefront propagated at a velocity much faster than that of sound through tissue. Shear waves are transverse waves of long duration and very low velocity, which produce gross distortions of tissues and organs.

Recent experimental studies[4] suggest that propagation of the stress waves described above may be the principal factor producing lung injury. Reinforcement and reflection of the pressure wave off the mediastinum causes a complex pressure environment within the lung parenchyma[5]. This is most pronounced at the alveolar–capillary membrane and results in pressure differentials across the barrier which allow leakage of blood into the alveolar spaces along with interstitial fluid. The low-velocity waves described above may cause shearing of lung tissue off the larger, more rigid bronchioles, causing further haemorrhage into the lung. Thus, the worst damaged areas generally appear where the stresses are greatest, in hilar and peripheral regions of the lung parenchyma.

Experiments done on animals during the Second World War showed that those within 18–30 ft of a 70 (31·5 kg) lb charge died of 'bilateral traumatic haemorrhage into both lungs. None survived at this distance, although others further away were not harmed in any way'[6]. This illustrates how rapidly the force of the blast wave drops away with distance.

With lesser degrees of blast, limited areas of blast contusion are seen. These may be related to the larger bronchioles or specific lobules. They do not seem to be very important clinically. Only two servicemen out of 828 suffered a degree of blast lung, with no external injury, which did not kill them but required ventilation for a period. It is likely that more severe but non-fatal degrees of blast lung occurred but were associated with other fatal injuries, or multiple injuries fatal in combination. Thus, looking at group 4 (*Table 4*), the majority died of multiple injuries as well as blast lung, although there were ten who appear to have died of their head injury alone.

Of deaths in group 4, 17 per cent occurred with no external injury. The majority of these probably died of blast lung, but a small percentage had inconclusive findings at post mortem. Air embolism has been cited as the cause of sudden death in these cases[3,7], and has certainly been demonstrated experimentally. Air embolism is also said to occur if blast victims are mechanically ventilated. There is no objective or experimental evidence for this and the phenomenon has not been commented on in any forensic report examined in this survey. This does not mean it does not occur, as air embolism is extremely difficult to detect unless specifically sought. It may be that in non-fatal degrees of blast lung there is insufficient damage for this to occur to any significant degree. The two servicemen who required mechanical ventilation for blast lung do not seem to have had any untoward effects in this regard. Cardiac dysrhythmias may occur as the blast wave passes, without any macroscopic or microscopic effect on the heart.

The number of deaths without external injury is higher than suggested by Cooper *et al.*[3], who were dealing with a civilian population. They maintain that sufficient proximity to the explosion to cause blast lung would entail equally fatal secondary missile injuries. This was the case in about one-third of the fatalities in this survey, but it is important to note that most of the injured wore body armour. Undoubtedly the body armour worn by most servicemen on patrol in the city would protect against penetrating chest injuries in the high blast group but not against the blast wave itself. There is some evidence to suggest that armour made of Kevlar® (Du Pont) may enhance the blast wave, although this effect is insignificant compared with the protection afforded against secondary missiles of both low and high velocity[8]. Both the survivors who required mechanical ventilation for blast lung had worn body armour and consequently had little in the way of external injury.

Head injury was the second most important cause of death and was a factor in 126 deaths and the sole injury in 26. It is tempting to surmise that deaths were caused by haemorrhage into the brain by shearing of vessels as the blast wave passed or motion of the brain within the skull. This may be true in the higher blast groups. However, most had evidence of external injury to the head so it is far more likely that the head was injured by flying debris, or by striking something when the victim was thrown by the explosion, particularly where head injury was the sole cause of death. Helmets were worn by less than 20 per cent of servicemen injured in this survey. Wearing helmets could have prevented deaths but at the expense of some mobility in the urban warfare environment.

Severe intra-abdominal injuries do not occur as an isolated phenomenon following exposure to blast, as the lung parenchyma is much more readily affected.

Looking at postoperative deaths following blast injury (*Table 5*), it is clear that chest and head injury decide survival. Blast injury severe enough to cause gut, liver or spleen injury usually causes fatal lung damage in air This is the case in the postoperative deaths in group 4, although those in groups 1 and 2, and to some extent group 3, died of their head injury. A notable exception is the first group 1 victim, who died of lung problems despite a relatively small explosion It may be that he developed adult respiratory distress syndrome (ARDS) as a result of his injuries rather than the blast itself. Where lung problems appear some time after the initial injury, it may be that some cause of ARDS other than blast should be invoked The post-mortem appearances will be much the same whatever the cause of ARDS.

There were only three survivors of laparotomy after an explosion, and they were all injured while in cars. This suggests that the injuries were due to compressive forces alone when the car was thrown by the explosion, and that the occupants were given some protection from the blast wave by the car body.

Those close enough to an explosion to suffer traumatic amputation are unlikely to survive the effect of the blast wave. Only nine of 52 suffering traumatic amputation survived. The remainder succumbed to chest or head injury.

In summary, a quarter of the 828 soldiers injured by explosions in Northern Ireland died. Chest injury was noted in three-quarters of the fatalities and, apart from a small group in whom no cause of death could be detected, the remainder died of head injuries. Sixteen patients died after surgery, of whom seven died of progressing ARDS. Whether the lung damage was primarily due to blast in these cases cannot be stated definitely. None of these deaths appears to have been avoidable. Only three patients survived laparotomy following explosions, and they were protected from the worst effects of the blast wave by being in cars.

By contrast, virtually all the injuries seen in survivors were caused by secondary missiles, rather than the blast wave itself. However, two blast victims without external injury survived lung damage severe enough to warrant mechanical ventilation. Such patients must be recognized and treated appropriately.

Body armour offers considerable protection against penetrating injury but is unlikely to protect against the effects of the blast wave. As a result, survivors of explosions wearing body armour may be seen with little in the way of external injury to the chest, but with more or less severe degrees of blast lung.

Research into the influence of armour on the pulmonary consequences of blast loading to the body and the most appropriate means of protecting the chest is continuing, with the aim of improving the chances of survival of servicemen exposed to terrorist bombings.

A prospective study has been undertaken of 321 patients with acute abdominal pain admitted to hospital under one surgical firm over a period of 21 months. During the first 10 months patients were classified on admission according to the perceived need for operation, with laparoscopy being performed on all those in whom the need for operation was uncertain. In addition, all women with suspected appendicitis underwent laparoscopy because previous studies by us and others have demonstrated a high error rate in this group. During the second 11 months of the study a similar system of classification and procedure was used but the patient's initial assessment was entered on a structured data sheet. After the patient had been discharged home this information was entered into a computer-aided diagnosis program. Hypothetical retrospective computer-aided decisions were then made about patient management. The final management error rate (correct decision to operate or not) was compared with the actual error rate using the clinical system. The final overall error rate in the first 10 months was 11 out of 163 patients and this was improved to 3 out of 158 in the second 11 months of the study by the addition of the structured data sheet to selective laparoscopy. A management policy based entirely on diagnostic probabilities taken from the computer-aided diagnosis program would have produced an error rate of 26 out of 158. We conclude that in the management of the acute abdomen a policy based on clinical decision combined with selective laparoscopy may be superior to one based on diagnostic probabilities alone. Further improvement in results follows the introduction of a structured data sheet for initial data collection.

Keywords: Acute abdomen, laparoscopy, computer, diagnosis

In the handling of the acute abdomen performance must be judged ultimately against the number of correct or incorrect clinical decisions – the management error rate. We have recently demonstrated the value of selective laparoscopy in the management of patients with acute abdominal pain[1] where the procedure is used in those patients in whom the clinical decision to operate is indeterminate. Further analysis of the results from this study demonstrated that without laparoscopy the incidence of removing normal appendices in women was twice that in men[2]. We therefore changed our practice so that all women with suspected appendicitis would undergo laparoscopy before appendicectomy, a policy with which many others agree[3–6], and this remains our practice.

There are, however, many other aids which have been demonstrated to improve performance in the management of the acute abdomen, e.g. computer-aided diagnosis[7,8], fine catheter aspiration cytology of the peritoneal cavity[9], ultrasonography[10,11], peritoneal lavage[12] and microwave thermography[13]. There can be little argument with the results produced by computer-aided diagnosis over the last 15 years. Not only can diagnostic accuracy be improved by 10–20 per cent[8,14] but when used in the accident and emergency department fewer patients are admitted to hospital[8,15]. Nevertheless, there has been reluctance to accept computer aided diagnosis for a variety of reasons[16]. These studies bring into question the whole principle behind the management of the acute abdomen. There are two pathways of management: one pathway is to reach a diagnosis from which subsequent management decisions can be based (this could be termed a clinicopathological diagnosis); the other pathway is making a clinical decision; does the patient require an operation or not (this could be termed a procedural diagnosis) In the management of the acute abdomen it is our opinion that surgeons focus intuitively more on the procedural than on the clinicopathological diagnosis.

To investigate this hypothesis we compared the outcome of a procedure-based management strategy that incorporated selective laparoscopy with a hypothetical strategy based on diagnostic probabilities.

Patients and methods

All patients with acute abdominal pain of less than 1 week duration, who were admitted to hospital under one surgical firm, were studied over a period of 21 months. Patients were referred directly from their local general practitioner or from the casualty officer and assessed in the emergency department by the duty surgeon (senior house officer/registrar). All patients were classified after emergency investigations into one of four groups (*Table 1*) within 6 h of admission according to the perceived need for urgent operation The emergency investigations included blood tests, X-rays and urine microscopy In normal instances when a clinician is uncertain whether an operation is required a 'look and see' or 'wait and see' policy would normally be adopted. A decision was therefore made in group C about which pathway would normally be followed without laparoscopy and then these patients underwent laparoscopy Thus the influence of laparoscopy on management could be evaluated Not all patients with acute abdominal pain are suitable for laparoscopy (*Table 1*) and we therefore included the 'exclusion from laparoscopy group' (group D) The management decision in this group was studied in the same manner as for the other groups Thus all patients admitted with abdominal pain were studied Patients with abdominal trauma were excluded,

Dyspepsia	1	
Patient 4		
Intestinal obstruction	68	Either
Diverticular disease	31	

because we use peritoneal lavage as the first line of investigation in this group, children (less than 16 years of age) were also excluded because we did not have a paediatric laparoscope In addition, patients were excluded if a definite diagnosis could be made of acute pancreatitis (serum amylase concentration >1000 units/l), perforated viscus (free intraperitoneal gas visible on a standing chest X-ray) or renal tract disease (demonstrated by urine analysis, ultrasound or intravenous urography) as laparoscopy has little extra to offer here This does not mean that patients with these conditions did not enter the other three groups, only that their diagnosis could not be confirmed with certainty following the initial investigations.

For the second 11 months of the study classification continued as above but the patients' clinical details were collected on a structured data sheet after admission. Once the patient had been discharged the data were entered on to a BBC Master computer by a third party and analysed using a computer-aided diagnosis program[8]. A hypothetical management plan was then derived from the diagnostic probabilities produced. Examples are given in *Table 2*. There are several diagnoses that can be associated with the need for either early surgery or a non-operative approach, depending on the clinical condition of the patient; these include acute cholecystitis and intestinal obstruction. We therefore decided to consider that if either of these diagnoses was made both the decision to operate or the decision not to do so would be considered correct. We used computer-aided diagnosis probabilities rather than the clinician's diagnosis for two reasons: it is generally accepted that computer-aided diagnosis improves diagnostic accuracy by 10–20 per cent[8,14]; and it could not be influenced by subconscious or intuitive factors. No attempt was made to investigate the possible influence of computer aided diagnosis on clinical performance had the results been available to the clinician 'on the spot'.

Any patients whose final diagnosis suggested that they should have undergone surgery sooner or, alternatively, did not require surgery were considered as incorrect management decisions. Patients placed into group B (urgent operation not required) who went on to elective surgery (e.g. cholecystectomy for acute cholecystitis) were not considered as management errors All laparoscopies were performed under general anaesthesia in a standard fashion[1].

Statistical evaluation

Comparisons between the error rates before and after laparoscopy is logical but hypothetical. For this reason it can be argued that statistical comparisons of this type are invalid and therefore they have not been made in this paper. However, it is our view that they allow comparison of two independent methods of subdividing the sample (all those in group C) One method splits the group on the basis of the management policy if laparoscopy had not been available; the other divides the group on the basis of the outcome of laparoscopy. The former is an unfulfilled prospective scenario. The null hypothesis is that the real outcome and the scenario will not differ. This prospective scenario method is discussed in more detail elsewhere[17]. The incorporation of computer-aided diagnosis probabilities is out of temporal context and therefore no statistical comparisons were made.

Results

In the first phase 163 patients were studied (*Table 3*). Two patients in group A did not need surgery and three patients in group B should have undergone surgery earlier. The two unnecessary operations in group A were an appendicectomy for non-specific abdominal pain and an open and shut laparotomy for metastatic carcinoma of the stomach. In group B one patient with a diverticular abscess and two with acute appendicitis were incorrectly thought not to require surgery after initial assessment. There were two errors in the group excluded from laparoscopy (group D); the patients underwent appendicectomy and in both a normal appendix was removed. However, 14 patients in group C would have had incorrect management without laparoscopy but this was reduced to four by laparoscopy (one patient with retrograde menstruation had a pelvis full of blood at laparoscopy and a laparotomy was performed, in three patients the appendix could not be seen adequately and so appendicectomies were performed, two had non-specific abdominal pain and one had pelvic inflammatory disease). These results confirm those of our previous studies[1]: selective laparoscopy can reduce the overall error rate, in this case from 21 of 163 to 11 of 163.

In the second phase when the data sheet had been introduced, the overall error rate was three of 158 (*Table 4*), again improved from a potential figure of 11 of 158 by selective laparoscopy. The one error in group B was another patient

Table 3 *Phase 1: before introduction of the structured data sheet*

Group	*n*	Errors
A	16	2
B	57	3
C	37	4*
D	53	2

B	55	1	6
C	35	0*	11
D	44	2	9
Total	158	3	26

* 8 before laparoscopy; CAD, computer-aided diagnosis

Table 5 *Errors in patients undergoing laparoscopy (Group C)*

Decision before laparoscopy	*n*
Phase 1	
Incorrect decision to 'look and see'	
Retrograde menstruation	1*
Non-specific abdominal pain	3 (2*)
Ruptured ovarian cyst	1
Incorrect decision to observe ('wait and see')	
Appendicitis	4
Torsion appendix epiploica	1
Small bowel obstruction (band adhesion)	2
Ectopic pregnancy	1
Bleeding ovarian cyst	1
Correct decision to observe	
Pelvic inflammatory disease (unnecessary appendicectomy after laparoscopy)	1*
Phase 2	
Incorrect decision to 'look and see'	
Pelvic inflammatory disease	2
Ruptured ovarian cyst	1
Incorrect decision to 'wait and see'	
Appendicitis	4
Ectopic pregnancy	1

* Incorrect decisions after laparoscopy: 4 of 72 (6 per cent)

with a diverticular abscess and the two errors in group D were again unnecessary appendicectomies.

The introduction of the structured data sheet improved the overall error rate from 11 of 163 in the first phase to three of 158 in the second phase. Overall 18 of 72 (25 per cent) patients who underwent laparoscopy avoided incorrect management decisions (*Tables 3* and *4*) and the clinical details and diagnoses of the errors in group C from both parts of the study are given in *Table 5*. A management strategy during this second phase based entirely on diagnostic probabilities, as produced by computer-aided diagnosis, would have resulted in an error rate of 26 of 158.

Discussion

This study formalizes what is known to all experienced clinicians about the management of the acute abdomen, namely that it is the recognition of which patients require early surgery that is the key to good clinical performance. However, there are still texts which place the emphasis differently, concentrating on attaining a clinicopathological diagnosis as a basis for action[18]. Our results reinforce the view that a procedural approach is more relevant.

The comparison that we made between the procedural attitude that we adopted and computer-aided diagnosis is 'unfair' to the latter It must be stressed that this study only compares two different management strategies, the one procedural-based and the other based on diagnostic probabilities. It makes no attempt to compare the influence computer-aided diagnosis would have had, if it had been incorporated into clinical practice with the results interpreted by the clinician on the spot. Although feasible to carry out, a formal prospective study that compares computer-aided diagnosis with laparoscopy-assisted decisions is complex. Therefore, computer-aided diagnosis was taken out of temporal context and arbitrary rules of interpretation of the diagnostic probabilities had to be used as a substitute for the clinician's incorporation of these into his decision about what to do. There is no doubt that computer-aided diagnosis improves diagnostic and procedural accuracy in the management of the acute abdomen[19–21]; however, it is well recognized that much of this change results from the use of a structured approach to data collection[8,22]. This study confirms the improvement in clinical performance associated with the use of a structured data sheet and has demonstrated that the same applies for procedural classification and laparoscopy. The final choice between using structured data collection with either computer ordering of diagnostic probabilities or selective laparoscopy is still open to the clinician. Both give excellent results. The marginal advantage of laparoscopy is that not infrequently it provides a precise diagnosis on which non-operative management can be based. However, the discipline, challenge and educational feedback imposed by computer-aided diagnosis should not be ignored[23].

Anastomotic aneurysms of the femoral artery: aetiology and treatment

A. M. Clarke, K. R. Poskitt, R. N. Baird and M. Horrocks

Department of Surgery, Bristol Royal Infirmary, Bristol BS2 8HW, UK

Correspondence to:
Mr M. Horrocks

The aetiology and treatment of 35 femoral false anastomotic aneurysms in 29 patients presenting over the 4-year period 1984–88 were reviewed retrospectively. The mean interval between primary anastomosis and false aneurysm repair was 6 years (range from 2 weeks to 16 years). Twenty-two (63 per cent) false aneurysms had occurred after previous aortobifemoral bypass grafting for occlusive aortoiliac disease. Seven (20 per cent) presented as acute surgical emergencies. Review of the records of the initial operations revealed that superficial wound infections with positive bacteriological cultures had been present in eight cases (23 per cent) and a further two (6 per cent) had lymph fistulae. Thirty-two false aneurysms were repaired, by simple reanastomosis in 14 cases, interposition grafting in 17 cases and in one case by complete revision to an aortobifemoral bypass graft. The risk of a further operative repair was less (P<0·05) following interposition grafting, than after simple revision. False aneurysm repairs, when compared with primary reconstructions done during the same period, were associated with more superficial wound infections (37 versus 10 per cent) and more explorations for haemorrhage within 30 days (19 versus 7 per cent).

Keywords: Anastomotic aneurysm, femoral artery

Despite their relatively low incidence (0·5–4 per cent)[1,2], non-infected anastomotic aneurysms continue to complicate arterial suture lines. Such aneurysms were thought to be due to fragmentation of silk sutures[3–6], but the change to synthetic non-absorbable sutures has not eliminated the problem. Risk factors are now thought to include excessive anastomotic tension[3,7–9], damage to the host artery wall by endarterectomy or suture-induced weakness[3,10–12], and alteration in the stress pattern across the anastomosis from underlying movements of the hip joint[13].

False aneurysms usually arise from weaknesses and disruption of the arterial wall adjacent to the anastomosis between the graft and the host artery. Blood escapes to form a communicating haematoma which is limited in size by the surrounding tissue. Although the interior of the false aneurysm sac contains thrombus and is usually lined by endothelial cells, there is an absence of medial and adventitial layers.

The femoral region is by far the most common site for anastomotic aneurysms. Satiani[14], in a collective review, reported that 79 per cent of 444 anastomotic aneurysms occurred in this region. Of 20 anastomotic aneurysms reported from Nottingham[15], 80 per cent were in the groin, but no site of an arterial anastomosis is exempt. Anastomotic aneurysms are much more common at the distal end of aortofemoral grafts than aortoiliac grafts, suggesting that local factors including hip flexion and excessive tension may have a role.

Patients and methods

Twenty-nine patients (27 male and 2 female patients) with 35 non-infective femoral false aneurysms secondary to arterial anastomosis in the groin were identified in a 4-year period between September 1984 and September 1988 inclusive. Primary and mycotic aneurysms, and false aneurysms from diagnostic femoral arterial cannulation and from intra-arterial injection by drug addicts were excluded. The diagnosis of false aneurysm was made on clinical grounds with confirmation by ultrasound and arteriography where indicated.

The false aneurysms repaired represented 4 per cent of 765 femoral artery anastomoses done during the period of study. The mean interval between primary arterial suture to false aneurysm repair was 6 years, with a range of 2 weeks to 16 years (*Figure 1*). Some original bypass and aneurysm operations were done elsewhere. Full details of the primary reconstruction were available from the case notes in 31 (88 per cent) and the remainder were obtained from other hospitals' notes and general practitioner reports. Other data recorded included age, sex and atherosclerotic risk factors.

Results

Primary reconstructive operation

The indications for the primary reconstructive procedures had been occlusive peripheral arterial disease in 29 (83 per cent) cases and aortoiliac aneurysm in six (17 per cent) cases. Twenty-two (63 per cent) false aneurysms occurred after aortofemoral bypass and eight (23 per cent) after iliofemoral bypass, with the remaining five (14 per cent) having occurred after a variety of other operations (*Figure 2*). Twenty-eight (80 per cent) were detected during routine follow-up and seven (20 per cent) presented as acute surgical emergencies, five (14 per cent) having ruptured and two (6 per cent) having thrombosed.

Six patients had bilateral anastomotic aneurysms at presentation and five (14 per cent) aneurysms had recurred at the same site following an earlier repair. Seven patients were hypertensive, none was diabetic and five had undergone more

than one groin exploration before developing a false aneurysm, e.g. an iliofemoral bypass revised to an aortobifemoral bypass In five (14 per cent) instances a femoral endarterectomy had also been performed at the time of the original bypass, and this may have weakened the arterial wall. Silk sutures were found in four cases and polypropylene had been used in the remainder.

A review of the records revealed that superficial wound infections with positive bacteriological cultures had been present in eight (23 per cent) lesions and a further two (6 per cent) had lymph fistulae. All patients who had had their primary operations in Bristol had received intravenous cephalosporin prophylaxis at the induction of anaesthesia. The type of graft that had been used at the original bypass was woven Dacron® (du Pont) in 17 (49 per cent) of the 35 cases and knitted Dacron in eight (23 per cent). The operating records in the remaining ten (29 per cent) cases did not distinguish between the two types.

Management of false aneurysms

All but three of the 35 false aneurysms were repaired surgically Of these three, two are small and in unfit patients, and one is asymptomatic, small and situated on the opposite side to a recently repaired anastomotic aneurysm. At exploration all the false aneurysms were found to be localized to the inguinal region with no extension above the inguinal ligament.

Technique of operative repair

Following aneursysmectomy, the method of revision was simple reanastomosis in 14 (44 per cent) cases and interposition grafting in 17 (53 per cent) cases. One aortounifemoral graft was revised to an aortobifemoral bypass Five interposition grafts were covered by the sartorius muscle to help prevent lymph fistulae.

Revision after simple and interposition repair

To date, six of the simple direct repairs have required further revision, five for recurrence of false aneurysm and one for thrombosis (*Figure 3*) This compares unfavourably with only one further revision for thrombosis in the interposition graft group (χ^2 with Yates' correction = 4·075; $P<0·05$). This suggests that the risk of a further operative revision being required is less with an interposition graft than with simple revision, despite the treatment option being decided by the surgeons' preference and not by randomization.

Healing following false aneurysm repair

In comparison with primary reconstructions done during the period of the study, false aneurysm repair was associated with an increased risk of postoperative complications: these included re-exploration for haemorrhage within 30 days of surgery (19 *versus* 7 per cent), and superficial wound infections (37 *versus* 10 per cent).

Discussion

There has been much controversy over the aetiology of anastomotic aneurysms of the femoral artery, with excessive anastomotic tension, superficial wound infection and hypertension as suggested causative factors. It seems likely that a degenerative process in the arterial wall at the suture line may cause separation of the host vessel from the prosthesis. Despite many authors finding intact suture on the grafts[3,11,16,17], dense fibrosis around the aneurysmal sac can make an accurate operative assessment of the anatomy very difficult We found no evidence of weakness in any of the grafts[18,19], although some dilatation of knitted grafts was noted[20]. Our data were insufficient to confirm or refute reports implicating previous endarterectomy[3,11,16]. The suggestion that local wound complications, including haematoma, lymph fistula and superficial wound infection[7,10,12,21,22] may lead to a ten-fold[23] increased chance of false aneurysm was supported in this study, although we could not confirm a recent report that superficial infection leads to a quicker destructive rate than sound healing without delay[12]. The risk of false aneurysm was not increased in hypertensives compared with normotensives, confirming the results of a Viennese study[12] and contrary to frequent assertions[1,2,11,14,16,21].

Poststenotic dilatation as a cause of false femoral aneurysm formation, due to the impingement of the common femoral artery on the inguinal ligament, has been reported[24] The inguinal ligament had been divided at the original reconstruction to avoid graft tethering but this procedure was not performed in any of our cases.

Our results favour the use of an interposition Dacron graft rather than simple reanastomosis as the treatment of choice because the latter is associated with an increased risk of a further false aneurysm[23]. Excessive anastomotic tension seems to be the most likely explanation of false aneurysm formation, as there have been no recurrent false aneurysms following the use of an interposition graft. Mechanical stresses in the region of the hip joint and tension in the direction of the graft axis expose the anastomosis to high shearing forces and this may also cause disruption of the Dacron–artery suture line. It is possible that false aneurysms may form early in the postoperative period if they are related to a local technical problem, e.g. a weak arterial wall, excessive tension, or wall damage from sutures. Teeuwen *et al.*[25] have recently demonstrated five anastomotic aneurysms in 234 aortic Dacron replacements within 3 weeks of bypass using intravenous digital subtraction angiography.

A reliable comparison with patients who had a similar bypass, but who have not developed a false aneurysm would be desirable, but it was difficult to find a matching operated population going back for 16 years. This is currently a subject under review using a prospective computerized vascular audit.

In conclusion, we suggest that careful follow-up after primary arterial reconstruction continues to be advisable, as false aneurysms left untreated can lead to complications. Only in small, asymptomatic, static cases, in high risk patients, should a conservative policy be used. To help minimize the risk of developing an anastomotic false aneurysm, scrupulous care must be taken at the initial reconstruction to avoid superficial wound infection. The graft should be free from tension and as generous amounts of artery wall as possible should be incorporated in the suture line. Femoral anastomotic aneurysms are best treated by interposition Dacron grafting rather than by direct repair.

Intervention for graft stenoses: the role of surgery and transluminal angioplasty

J. F. Thompson, M. D. McShane, the late P. C. Clifford, V. Gazzard, J. H. Webster and A. B. Chant

Vascular Surgical Unit, Royal South Hampshire Hospital, Southampton SO1 4PE, UK

Correspondence to: Mr J. F. Thompson

Femorodistal grafts have a high rate of failure in the first 2 years after operation[1], and the rapid development of stenoses in such grafts seems to be a prime cause[2]. The development of non-invasive techniques, such as ankle:brachial pressure indices and duplex scanning, permits intensive surveillance and identification of grafts at risk at an early stage[3–5]. Appropriate intervention can then be planned before graft thrombosis can occur. Since 1985, all patients undergoing femorodistal reconstruction in this unit have been followed prospectively. The results of intervention for graft stenosis are presented and the role of percutaneous transluminal angioplasty is debated.

Methods

Patients were reviewed in the vascular laboratory 6 weeks after operation and, thereafter, at 3-monthly intervals or more regularly, if indicated. The techniques used, which have been described before[3], included clinical assessment, measurement of ankle:brachial pressure indices before and after stress, and duplex ultrasonography of the graft. Digital subtraction angiography was performed for clinical deterioration, a fall in the ankle:brachial pressure index of >0.2, or a haemodynamically important stenosis detected by duplex scanning. Proximal stenoses were treated by formal surgical revision (jump graft or patch angioplasty), and intragraft or distal anastomotic stenoses were treated by percutaneous transluminal angioplasty using an antegrade puncture. Sustained high pressures (12–15 atm for 5 min) were often required to dilate graft related stenoses successfully. An initial technical success rate of 100 per cent was confirmed by angiography and duplex ultrasonography. There were no cases of anastomotic disruption or false aneurysm formation.

Results

Two hundred and six femorodistal reconstructions were performed during the 15-month period ending in January 1987. In 105 reconstructions *in-situ* vein was used, 98 used prosthetic material, two used reversed vein and one used umbilical vein. The large number of prosthetic grafts reflected a preference for synthetic material for above knee reconstructions in order to preserve the long saphenous vein for more distal bypass or coronary artery surgery.

Twenty-two stenoses were identified in vein grafts, at a mean of 8 months after operation. Nineteen were treated immediately because of deteriorating ankle:brachial pressure indices or because they were high grade (>75 per cent diameter) according to duplex derived velocity criteria. Of these 19 patients 17 were asymptomatic. Three stenoses, causing a fall in pressure index of <0.2 or that were low grade according to duplex criteria, were observed, but all progressed far enough to require revision within 3 months of first identification.

Of six proximal anastomotic stenoses treated by formal revision, five remained satisfactory at 15 months follow-up. One graft occluded 16 months after revision. Following successful transluminal angioplasty, nine distal anastomotic lesions were kept under close surveillance; all recurred within 6 months. Of seven similarly treated intragraft stenoses, six recurred within 6 months. One intragraft lesion, however, remained satisfactory after 18 months follow-up.

Discussion

Haemodynamically important graft stenoses can now be rapidly identified using non-invasive techniques[3–5], especially with the advent of colour coded duplex ultrasonography. High throughput and low cost per patient make this an economical approach. As most graft stenoses occur in the first 3 years after surgery, it would not appear necessary to employ such follow-up indefinitely.

The most appropriate treatment for graft stenosis remains in doubt. Percutaneous transluminal angioplasty is attractive because of its ease and simplicity, but our experience has been disappointing as restenosis seems almost universal and rapid. The reasons for this are unclear but it is recognized that infrainguinal angioplasty yields lower long term patency rates than aortoiliac angioplasty[6,7]. More importantly, the type of lesion within a graft differs from atherosclerotic plaque, which is amenable to fracture and remodelling[8]. Early graft stenosis is presumably caused by fibrosis or anastomotic neointimal hyperplasia. Dilatation of a fibrotic lesion may exacerbate fibrosis, and does nothing to prevent the progression of intimal hyperplasia. Because of this and our current experience, we conclude that a randomized trial of surgical revision and percutaneous transluminal angioplasty is needed to determine the best method of 'graft maintenance'.

Between January 1980 and September 1988, 34 octogenarians underwent aortic aneurysm repair. There were 26 men and eight women with a median age of 83 years (range 80–88 years). Twenty underwent 'emergency' repair after presenting with pain and/or collapse: 11 with a retroperitoneal rupture, three with an intraperitoneal rupture and six with an expanding aneurysm. The mortality rate for this group was 35 per cent. During the same period 14 patients had an elective repair and there were no deaths within 30 days. The mean hospital stay for the elective group was 14·2 days compared with 17·0 days for survivors in the emergency group. There was no significant difference in terms of risk factors between those who developed postoperative complications and those who did not. These mortality rates compare favourably with our overall mortality results for elective (4·6 per cent) and emergency (31 per cent) surgery. Those patients over 80 years of age with infrarenal abdominal aortic aneurysms should not be refused surgery on the basis of age alone; each patient should be judged individually.

Keywords: Aortic aneurysm, octogenarian

Surgical repair of aortic aneurysm in the elderly has been a controversial issue in recent years and has been highlighted in the UK by the recent Confidential Enquiry into Perioperative Deaths (CEPOD)[1]. This suggested that patients over 80 years of age with ruptured abdominal aortic aneurysm are unlikely to survive surgery and, therefore, should not be operated on.

Elderly aneurysm patients are known to tolerate blood loss poorly and concurrent systemic disease, such as coronary heart disease, causes an increased risk of perioperative complications[2]. Nevertheless, improvements in anaesthetic and surgical technique have reduced morbidity and mortality and have led to an improved outcome in high risk groups, including the elderly. Ammar reported a mortality rate of 7·8 per cent for elective aneurysm repair in patients over 80 years old, which compared favourably with his statistics for those under 80 years[3]. Selection of patients for surgery in the older age group has to take into account physical factors such as coronary heart disease as well as social and psychological factors. The older age group may include patients who have a poor quality of life owing to mental or physical handicap, from being wheelchair bound or from coexistent malignant disease. Although all these can be present in those under 80 years of age, they are more common in the older age group.

The increased awareness of the medical profession to the risks of abdominal aortic aneurysm, and the development of ultrasound as a diagnostic tool have resulted in an apparent increase in the incidence of the condition[4,5]. As the general population ages, more octogenarians will present with abdominal aortic aneurysm. The purpose of this study was to examine the mode of presentation, treatment and outcome of patients over 80 years of age with infrarenal abdominal aortic aneurysm.

Patients and methods

Details were obtained of all infrarenal abdominal aortic aneurysm repairs carried out at the Bristol Royal Infirmary between the years of 1980 and 1988. For the first 4 years case notes were used but from September 1984 the details were obtained from a prospective computerized vascular audit. Thirty-four octogenarians (age range 80–88 years, with five patients over 85 years of age) underwent operation out of an overall total of 311 patients undergoing aortic aneurysm repair. Patients were divided into two groups, 'elective' and 'emergency'. The emergency group consisted of (1) 'expanding aneurysms' (patients presenting with severe pain but no extravasation of blood at operation); (2) retroperitoneal rupture; and (3) intraperitoneal rupture. Using a computerized audit system the following details were recorded: risk factors, presentation, general and surgical complications, mortality and cause of death, and length of hospital stay

Results

Of the 34 octogenarians undergoing aortic aneurysm repair, 26 were men and eight were women, with an age range of 80–88 years. Of these, 20 underwent emergency and 14 elective repair (*Figure 1*). There were no cases of inflammatory aneurysm or of horseshoe kidney. It was not possible to obtain details of how many octogenarians were not offered surgery because their general practitioner did not refer them or because the surgeon felt that surgery was inappropriate. All patients who arrived in the accident department alive were transferred immediately to theatre. No patient could be identified who was refused surgery at this stage. There were no reports to the coroner during the study period of any deaths in the community due to ruptured aortic aneurysm in this age group, although it is inevitable that some who died of ruptured aneurysm were not reported. Alternatively, the cause of death may have been ascribed to some other pathology such as myocardial infarction.

Of the 14 elective repairs nine were in asymptomatic patients and five were in symptomatic patients, all of whom complained of back pain. All 14 patients with elective repairs left hospital alive; there were no deaths within 30 days of operation. This compared with a mortality rate in our overall elective series of 4·6 per cent.

Of the 20 patients undergoing an emergency repair six had expanding aneurysms with no evidence of rupture, 11 were retroperitoneal ruptures, and three were intraperitoneal rupture (*Figure 1*). Seven of the 20 octogenarians undergoing emergency repair died (*Table 1*). This mortality rate of 35 per cent compares favourably with that of 31 per cent for all emergency repairs (116 patients) over the same time period. One patient, who died during surgery, presented with an intraperitoneal rupture and an aortocaval fistula; he had had his aneurysm wired 12 years previously. One patient died in oliguric renal failure 2 weeks after a massive perioperative blood transfusion. Another died 2 days after operation from renal failure, having sustained several hours of hypotension during transfer from

Adult respiratory distress syndrome	1

another hospital 20 miles away. Two patients died from myocardial infarction several days after an apparently uncomplicated operation. One patient, who presented with an intraperitoneal rupture, died on the day of operation from disseminated intravascular coagulation and another patient developed adult respiratory distress syndrome and died on the 12th day after surgery.

Risk factors were as follows: four patients were hypertensive, four suffered from coronary heart disease and three had renal impairment. However, there was no significant correlation between the presence of cardiovascular risk factors and subsequent postoperative morbidity and mortality. Postoperative complications occurred in 14 patients. The commonest complication was chest infection, occurring in eight of the 27 survivors. The average hospital stay for all patients undergoing elective operation was 14·2 days, while for the survivors of emergency procedures it was 17·0 days.

The most common repair was with a straight Dacron® (du Pont) graft, which was used in 18 out of 20 (90 per cent) emergency procedures. In one case a bifurcated graft was used for a retroperitoneal rupture in which the aneurysm involved the common iliac arteries. One patient died before a prosthesis was sewn in. In the elective cases, bifurcated grafts were used on six occasions (42 per cent); two of these patients had iliac artery aneurysms. A knitted prosthesis was used on only two occasions, and no polytetrafluoroethylene grafts were inserted.

Discussion

Our study provides results comparable to those from previous work elsewhere. In a series of 86 octogenarians, O'Donnell reported an overall mortality rate for a non-ruptured group of 4·7 per cent, with a 74 per cent mortality rate for a ruptured group[6]. In contrast Esselstyn reported a higher elective mortality rate of 14 per cent in 152 patients aged 75 years and above, compared with an overall 9 per cent mortality rate. Of his 'emergency' patients 63 per cent died[7]. Sterpetti divided patients into high and low risk groups according to the number and severity of associated risk factors. In the high risk group, the operative mortality rate was 39·8 per cent compared with 4·3 per cent in the low risk group[8]. He adopted a policy of serial ultrasound follow-up on patients with small aneurysms but observed that although operative mortality in high risk patients may be high, a large aneurysm left alone is a constant threat to life. Edmunds recommended resection in octogenarians only for ruptured, expanding or newly symptomatic aneurysms[9], but this policy may lead to a higher risk of operative mortality than offering resection on an elective basis, especially in those patients with large aneurysms.

Bjerkelund showed that coronary heart disease and renal failure were the most important risk factors[2]. Szilagyi[10] observed that arterial hypertension was associated with subsequent aneurysm rupture and suggested that hypertensives should not be excluded from surgery on the basis of blood pressure alone. In our series, four patients were hypertensive and four had coronary heart disease but the presence of these risk factors was not significantly associated with subsequent morbidity or mortality.

Fourteen out of the 27 survivors had one or more general complications, most commonly a chest infection. This compares with the postoperative complication rate of 54 per cent described by Treiman *et al.*[11]. All of their patients had undergone elective aneurysmectomy.

An argument put forward against operating on octogenarians with aneurysms relates to their relatively short postoperative life expectancy. O'Donnell compared three groups of patients with aneurysms who were over 80 years of age with octogenarians without aneurysms. The survival curve for those undergoing elective surgery matched that of the general population, while that for the ruptured group showed an initial sharp decline followed by a more gradual decline over the months after successful surgery. Patients with aneurysms not treated by elective surgery had a much shorter life expectancy than that of the general population. Szilagyi studied a group of patients who were not offered aneurysmectomy due to a variety of complications (patients over 80 years of age were generally excluded). Of these unoperated patients, 27·8 per cent died from a ruptured abdominal aortic aneurysm over a 20-year follow-up period, this being the second commonest cause of death after coronary heart disease in his series. Szilagyi observed that with advancing age other degenerative diseases contributed to a reduced life expectancy, as well as operative mortality. However, advanced age accounted for only 12 per cent of operative contraindications in his series, confirming O'Donnell's findings that age *per se* was only of prognostic significance when expressed in physiological rather than chronological terms.

In our current series the ratio of emergency to elective aneurysm repairs increased with age. This may reflect the referring practices of the local general practitioners who may not screen the older age group or refer them for a surgical opinion. This observation is supported by the work of Petracek[12] who found that 51 per cent of primary health care physicians said they would not refer octogenarians with abdominal aortic aneurysms for consideration for surgery. He suggested that these physicians had made an incorrect assessment of operative risk in this age group.

Our results show that in a selected group of octogenarians the operative mortality and morbidity rates were similar to those in non-octogenarians. It is more cost-effective to operate electively rather than as an emergency. Size is not necessarily a good guide to impending rupture[8] and so all octogenarians with an infrarenal abdominal aortic aneurysm should be considered for surgery, although it is probably safe to keep under observation any aneurysm less than 4·5 cm in diameter[13].

In summary, this review of octogenarians undergoing surgery for aortic aneurysm over the last 8 years shows that the results in both elective and emergency repair compare favourably with our overall results and with the results of other series. We conclude that the CEPOD recommendation not to operate on octogenarians with ruptured aneurysms is unjustified and that all patients should undergo the same selection criteria for operation regardless of age.

Simultaneous readings of transcutaneous partial pressure of oxygen (P_{tc,O_2}) *were obtained from the left anterior chest wall, from 10 cm distal to the medial aspect of the knee joint, and from the first dorsal webspace in 16 patients with acute peripheral arterial ischaemia of the leg. Oxygen was administered at concentrations of 24, 40, 60 and 100 per cent. Mean(s.d.) initial chest* P_{tc,O_2} *(53 (17) mmHg) was significantly higher than that of the medial lower limb site (37(17) mmHg). After inhalation of 24 per cent oxygen, a statistically significant* ($P<0\cdot025$) *increase in chest* P_{tc,O_2} *was achieved (63(20) mmHg), but the increase in* P_{tc,O_2} *(43(19) mmHg) at the medial lower limb site was not statistically significant. Inhalation of 40 per cent oxygen resulted in significant increases at both sites (chest: 83(23) mmHg,* $P<0\cdot01$*; limb: 53(26) mmHg,* $P<0\cdot05$*).* P_{tc,O_2} *in the limb at this concentration of inhaled oxygen was equal to the initial chest level. Increasing the oxygen concentration to 60 per cent and then to 100 per cent produced further significant* ($P<0\cdot001$) *increases in* P_{tc,O_2} *at both sites. The use of continuous oxygen inhalation during acute ischaemia may improve tissue nutrition before, during and after definitive treatment.*

Keywords: Transcutaneous oxygen, acute arterial ischaemia

Transcutaneous partial pressure of oxygen (P_{tc,O_2}) measurements have been shown to be useful in the assessment of amputation level[1,2] and in the determination of the severity of arterial ischaemia[3–7]. In the management of acute arterial ischaemia the distinction between thrombosis and embolism and the severity of that ischaemia determine the type and timing of intervention. In the case of embolism this will be in the form of balloon embolectomy[8] or high dose heparin therapy[9]. Patients with acute thrombosis will require surgical reconstruction[10] or thrombolysis, in an attempt to achieve limb salvage[11–13]. In these patients few additional therapies to reduce tissue damage are of proven value. Some authors advocate heparin to reduce the risk of propagation of the thrombus which may make surgery or thrombolysis more difficult[9,10]. However, the role of continuous oxygen therapy has not been addressed. Administration of 100 per cent oxygen has been shown to produce significant increases[14] in limb P_{tc,O_2}, but this is obviously impractical as a continuous therapy. As part of our assessment before consideration of thrombolytic therapy, we have evaluated the effects of a range of inhaled oxygen concentrations on the P_{tc,O_2} of the lower limb in 16 patients with acute peripheral arterial ischaemia of the leg.

Patients and methods

Sixteen patients with acute peripheral arterial ischaemia of the leg were studied. There were 14 men and two women with a mean(s.d.) age of 72(9) years The mean(s d.) ankle:brachial systolic index was 0 12(0 17), and nine patients had inaudible ankle Doppler ultrasound signals. Eight patients had rest pain alone and eight had rest pain and gangrene. Three patients were diabetic. Seven patients had diminished or absent sensation in the affected limb, usually confined to the dorsum of the foot No patient had motor paralysis. The mean(s.d.) duration of acute ischaemia was 14(10) days

P_{tc,O_2} readings were made using a Radiometer Dual Channel TCM2 (Radiometer, Coventry, UK) with standard platinum electrodes. Both electrodes were calibrated before each recording. Three sites were assessed: left anterior chest wall, 10 cm distal to the line of the medial aspect of the knee joint, and the first dorsal web space on the affected limb Readings were obtained simultaneously from the chest wall and the dorsum of the foot or lower limb. All patients were rested supine, to allow equilibration for 30 min before obtaining baseline P_{tc,O_2} readings. Baseline P_{tc,O_2} was then assessed at each site with the electrode temperature set at 44°C. A stable reading was confirmed by a plateau on the chart recorder and a constant heat output Oxygen was then administered via a face mask with variable venturi connectors to achieve oxygen concentrations of 24, 40 and 60 per cent according to the manufacturers guidelines (Controlled Percentage Kit, Intersurgical Complete Respiratory Systems, Twickenham, UK). A closed circuit, incorporating a non-return valve in association with a Waters' bag (Ohmeda, Harlow, UK), was used to administer 100 per cent oxygen via a standard anaesthetic face mask. The maximum plateau reading was recorded for each oxygen concentration before increasing the concentration to the next level All patients gave informed consent.

Results are expressed as mean(s.d.) unless otherwise specified Statistical analysis was performed using the Mann–Whitney *U* test.

Results

Initial anterior chest P_{tc,O_2} (mean(s.d.) 53(17) mmHg) was significantly higher than that from the medial lower limb site (37(17) mmHg, $P<0\cdot025$), and from the dorsum of the foot (1(3) mmHg, $P<0\cdot0001$; *Table 1*). After inhalation of 24 per cent oxygen, significant increases ($P<0\cdot025$) in chest P_{tc,O_2} were achieved (63(20) mmHg) but only minimal increases in medial lower limb P_{tc,O_2} (43(19) mmHg). Inhalation of 40 per cent oxygen resulted in significant increases at both sites (chest: 83(23) mmHg, $P<0\cdot01$; medial lower limb: 53(26) mmHg, $P<0\cdot05$). At this point P_{tc,O_2} in the limb was equal to the initial chest level. Increasing the oxygen concentration to 60 per cent and then to 100 per cent produced further significant ($P<0\cdot001$) increases in P_{tc,O_2} at both sites (*Figures 1* and *2*) However, at the dorsal foot site administration of even 100 per cent oxygen failed to produce a consistent increase in P_{tc,O_2}. Lower levels of oxygen concentration were not assessed at this site.

The oxygen perfusion index (OPI) was calculated as follows:

$$\mathrm{OPI}=\frac{P_{tc,O_2}\ \text{limb on } O_2 \text{ (at specified concentration)}}{P_{tc,O_2}\ \text{initial chest (on air)}}$$

This allows an assessment of the improvement in peripheral tissue oxygenation following oxygen administration, compared with the maximum resting tissue perfusion for that patient (i.e over the chest wall). There is a significant increase in this index

using 40 per cent oxygen ($P<0·05$), with further increases using 60 and 100 per cent oxygen (*Figure 3*).

Discussion

Despite using an electrode temperature of 44°C, marked individual differences in P_{tc,O_2} undoubtedly still occur due to variability in skin thickness and vascularity[15,16]. Initially, P_{tc,O_2} was thought to correlate with arterial oxygen tension[17,18] but later studies showed it to correlate with oxygen delivery[19–23]. This may explain the failure of increased concentrations of inspired oxygen to enhance P_{tc,O_2} at the dorsal foot site. With extremely low blood flow in an ischaemic foot, blood may be diverted away from skin capillaries, hence any rise in blood oxygen content may be already taken up by the time that blood reaches skin capillaries. Attempts to improve the ability of transcutaneous oxygen monitors to differentiate disease states or to predict healing at amputation levels has involved the use of positional changes[24], regional perfusion indices[25], exercise stress testing[26], postischaemic hyperaemia[5] and the rate of rise of P_{tc,O_2} following inhalation of 100 per cent oxygen[14].

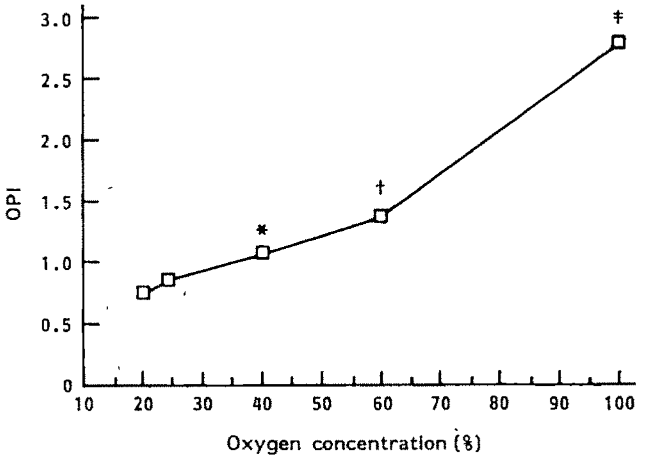

Figure 3 *The effect of concentration of inspired oxygen on the oxygen potential index (OPI).* * $P<0·05$, † $P<0·01$, ‡ $P<0·001$ (*Mann–Whitney* U *test*)

There is a large increase in P_{tc,O_2} following 100 per cent oxygen administration but this is obviously not a practical proposition for continuous use. However, our study has shown that even with 24 per cent oxygen an increase in P_{tc,O_2} is seen, which becomes statistically significant in the compromised limb using 40 per cent oxygen. Furthermore, the oxygen perfusion index using 40 per cent oxygen had a mean value of 1·05. In other words, the P_{tc,O_2} in the lower limb is significantly higher than the probable maximum resting P_{tc,O_2} in that patient. Administration of 60 per cent oxygen produced a further significant increase in P_{tc,O_2} over the anterior chest wall ($P<0·001$), but it did not produce a commensurate increase at the medial lower limb site ($P>0·05$).

The mean(s.d.) initial chest value in our study (53(17) mmHg) is lower than might be expected. Although increasing age is known adversely to affect P_{tc,O_2}[27], the mean(s.d.) age of our patients was 72(9) years and one might have expected a mean P_{tc,O_2} of approximately 75 mmHg. The low value obtained may reflect the generalized nature of arterial disease in our patients, with associated cardiorespiratory insufficiency.

Although the oxygen concentrations are quoted as 24, 40, 60 or 100 per cent, we readily admit that the actual oxygen concentrations received by the patients were probably less than these. Nevertheless, the experiment reflects clinical practice and we believe the results are clinically valid. We did not perform simultaneous arterial partial pressure of oxygen measurements as the patients were due to receive thrombolytic therapy.

There are several clinical situations in which continuous oxygen may be of help. In patients with ischaemic ulcers, we may be able to accelerate healing by increasing local oxygen concentration[28]. Distal tibial revascularization is also associated with reduced skin oxygenation for up to 7 days after surgery[29,30] and oxygen therapy may be of benefit. Patients with ischaemic rest pain obtain some relief from their symptoms by hanging the leg outside the bed. In the dependent position an increased $P_{\mathrm{tc,O_2}}$ at the foot is seen[24] which could be further augmented by oxygen inhalation.

Adjunctive therapy with continuous oxygen inhalation may help to protect ischaemic tissues while awaiting definitive intervention or during peripheral arterial thrombolysis. It could also be used in the early postoperative period after amputation to aid wound healing[31]. Although significant elevation of $P_{\mathrm{tc,O_2}}$ was seen at the medial lower limb site rather than over the dorsum of the foot, adjunctive therapy may still be of use in acute ischaemia by avoiding or reducing the delayed tissue oxygenation associated with reconstruction[29,30]. Further studies are required to assess these potential benefits in clinical practice. Unless the patient is known to suffer from severe chronic obstructive airways disease, 40 per cent oxygen administration is not a hazard. As a precaution a capillary or arterial blood gas estimation can be performed to exclude chronic carbon dioxide retention.

New radionucleotide method of visualizing subclavian vein occlusion following temporary venous access

P. K. Donnelly, I. Belton*, P. Chapman and E. M. Watkin†

*Departments of Surgery, *Medical Physics and †Radiology, Leicester General Hospital, Gwendolen Road, Leicester LE5 4PW, UK*

Correspondence to: Mr P. K. Donnelly

Subclavian vein catheterization is an increasingly popular access route for nutrition, chemotherapy and haemodialysis[1,2]. In a recent national survey 83 per cent of renal units favoured subclavian vein cannulation as the method of access in acute renal failure or in chronic renal failure for patients awaiting permanent access[1]. Subclavian vein stenosis and thrombosis are unfortunately now recognized as serious long-term complications of subclavian vein cannulation[2,3]. Systematic radiological screening has been performed in some studies, which report the incidence of complete or partial vessel occlusion as ranging from 19 to 50 per cent. Even an occult stenosis may become clinically obvious, with the formation of arm oedema and a collateral circulation, when an arteriovenous fistula is created on the same side for haemodialysis[4]. Surgical venous reconstruction, streptokinase therapy, balloon angioplasty and ultimately ablation of the fistula by ligation may be necessary to relieve this complication[4,5]. Hence there is a need to image the subclavian vein. Classically this is achieved by radiographic venography, but radioisotope venography is quicker and cheaper, and has been used in the upper limbs when there was clinical evidence of venous occlusion[6,7]. Ultrasound imaging, especially duplex imaging with Doppler, computed tomography and digital subtraction angiography have also been described, but are relatively costly and time consuming[8,9]. The aim of this study was to investigate subclavian vein patency in patients previously treated by temporary venous cannulation for haemodialysis and to compare the results of radiographic venography with those of radioisotope imaging using technetium-99m pertechnetate.

Patients and methods

Forty combined investigations were performed on 20 patients suffering from end-stage renal failure. There were 15 men and 5 women aged 20–70 years (mean 58·6 years). All patients had previously required temporary subclavian vein catheterization for haemodialysis on one or both sides and some several times (median number of catheters per patient 1, range 1–6). Cannulae were inserted on the right side alone in 12 patients, on the left alone in one, and on both sides in seven. The right side was most commonly used for first catheterization as this is generally believed to be a technically easier site for insertion. In each case the cannula used was a double lumen Quinton–Mahurkar® (Quinton Company Ltd., Seattle, USA). As a result of subclavian vein cannulation, four patients had previously experienced complications which had resolved at the time of the study: one patient developed a pneumothorax, one a transient numbness of the arm, and two had septicaemia. For each patient the total duration of temporary subclavian access was recorded. At the time of the study all patients were being treated by continuous ambulatory peritoneal dialysis and none had clinical signs or symptoms of subclavian vein stenosis.

For the radiographic venogram the patient lay supine on the X-ray table with the arm slightly abducted. Iopamidol (Niopam 300®, E. Merck Ltd., Four Marks, UK) was injected as a 25-ml bolus into a vein in the antecubital fossa using a 20-gauge Mediport® (Sherwood Medical, Tullamore, Ireland) cannula; films were taken to show the subclavian vein, and the veins were then flushed with saline. The procedure was repeated on the other side. The cannulae were left in the veins and the patient was taken to the nuclear medicine department for the radioisotope venogram. The patient lay supine on the γ camera table with the arms slightly abducted. Technetium-99m pertechnetate 80 MBq was injected as a rapid bolus into the veins of both arms simultaneously. A sequence of images was acquired for 20 s, and later they were processed and displayed on film. The radiographic and radioisotopic venograms were reported independently by an experienced radiologist without knowledge of previous catheterization details of the patients.

Results

The radiographic and radioisotopic venograms were reported as being normal, occluded or flowing slowly through the subclavian vein. Examples of an abnormal radiographic and

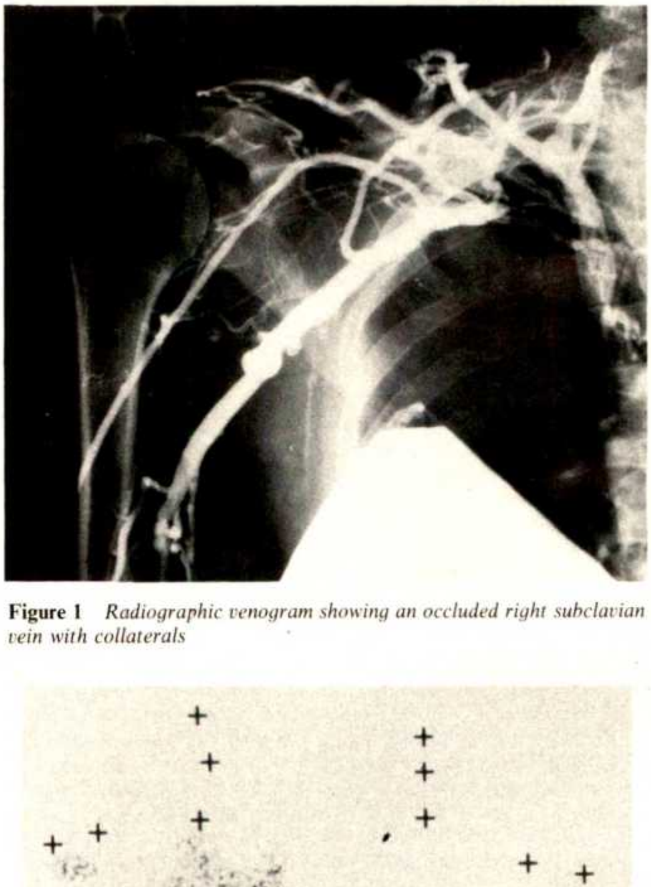

Figure 1 *Radiographic venogram showing an occluded right subclavian vein with collaterals*

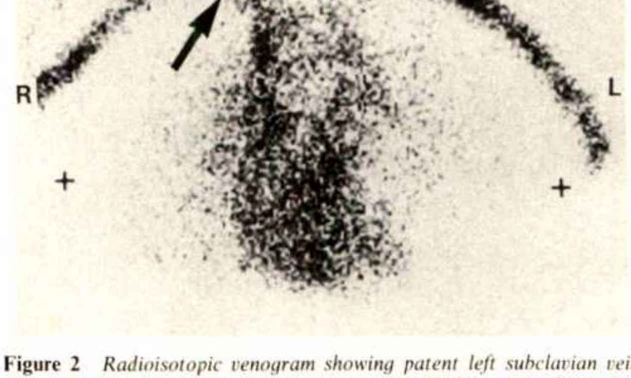

Figure 2 *Radioisotopic venogram showing patent left subclavian vein and occluded right subclavian vein (arrowed) with filling of collaterals*

radioisotopic venogram are shown in *Figures 1* and *2*. Of the 40 scans performed 37 (92 per cent) were reported in agreement. Three occlusions were seen by both methods and represented 11 per cent of 27 subclavian veins previously cannulated. The investigations also agreed in showing slow flow in the subclavian vein of two patients, although the significance of this is uncertain. Slow flow was seen once on a radioisotope venogram but not on the corresponding radiographic venogram and once radiographically but not on the isotope venogram. A subclavian vein filling defect was seen on one radiograph and again its significance is uncertain as all patients were asymptomatic. Occluded subclavian veins occurred in three of the seven patients (43 per cent) who had received multiple bilateral subclavian vein catheterization. One patient had previously had four cannulae inserted in the vein that became occluded, and the other two patients had each had two cannulae in their occluded vein. Most patients (55 per cent) had single vessel cannulation; six had two or more cannulae *in situ* without apparent damage to their subclavian veins. Although two patients with subclavian vein occlusion had been using temporary access for up to 14 weeks (compared with a median of 4·5 weeks, range 1–41), there were insufficient data to comment on a relationship between venous occlusion and duration of cannulation.

There were two apparent delayed reactions to radiographic contrast, beginning respectively 6 and 16 h after venography. Both patients had an acute painful polyarthropathy with nausea and vomiting. Both were treated with non-steroidal anti-inflammatory drugs and made a full recovery. The first patient had had no previous joint problems. The second patient had a history of rheumatoid arthritis, but had been symptom-free for the previous year.

Discussion

In this study the radioisotopic venography proved 100 per cent accurate in the diagnosis of occult venous occlusions when compared with conventional radiographic venography. The relatively low incidence of subclavian vein occlusion may be attributable to operator skill in catheter placement and the preferential use of the right side. Although there were clear associations between the occurrence of venous occlusion and previous multiple or prolonged cannulations, these criteria are far from being diagnostic. Subclavian vein occlusion has been reported after a single short-term venous cannulation[3]. Aetiological factors in the development of vascular stenosis are believed to be prolonged contact between catheter tip and vessel wall, resulting in intimal damage, and the oscillation of the catheter during dialysis. To reduce the risk of proximal venous occlusion in a limb required for an arteriovenous access procedure, temporary venous access should be kept to a minimum and permanent procedures planned in advance of need. When acute access is required, the use of the dominant arm (normally the right) leaves the non-dominant arm available for subsequent arteriovenous fistula formation. The increased use of jugular venous access may further reduce the likelihood of proximal venous occlusion[10]. However, where it has been necessary to cannulate both arms or when the forearm veins are only suitable for fistula formation on a previously cannulated side, the simple preoperative radioisotope method described for visualizing the subclavian veins is likely to be of considerable value. There are no known reactions to technetium-99m pertechnetate. Although iopamidol, the radiographic contrast medium, is suspected of being the cause of the mild reactions, it is a very safe non-ionic low osmolar contrast medium. Contrast sensitivity of any sort is rare. Although early reactions have occurred in renal failure patients[3], there seems to be no record of similar delayed reactions. Iopamidol is normally excreted rapidly via the kidneys, but this may be delayed in patients on continuous ambulatory peritoneal dialysis.

Radioisotope subclavian venography has been found to be a quick, cheap, safe and reliable method of assessing subclavian vein patency in patents with renal failure.

Acknowledgements

The authors are most grateful to nephrologists, Dr J. Walls and Dr J. Feehally, whose patients were included in this study. We are also grateful to Miss S. Massey, who typed the manuscript, and the Department of Medical Illustration for the figures.

Despite increasing success with low-dose intra-arterial thrombolysis, early rethrombosis still occurs. Platelet aggregation is thought to play a major part in this process. We have therefore investigated the effects of recombinant tissue plasminogen activator (rt-PA) and streptokinase on platelet function at doses currently used for peripheral arterial thrombolysis. Platelet-rich plasma was stirred at 37°C, with either streptokinase (100, 300 or 1000 units ml^{-1}) or rt-PA (10 (T10), 30 (T30) and 100 (T100) mg l^{-1}), with immediate addition of an agonist for platelet aggregation (thrombin, collagen, adenosine diphosphate (ADP) or adrenaline) at a predetermined threshold dose. Significant inhibition of collagen-induced and adrenaline-induced platelet aggregation was produced with rt-PA at all doses used ($P<0{\cdot}05$). With adrenaline as the agonist, T100 produced disaggregation to a mean(s.d.) level of 26 (11) per cent. Thrombin-stimulated platelet aggregation was significantly reduced by T100 ($P<0{\cdot}001$) and T30 ($P<0{\cdot}01$) only, disaggregation being dose-dependent and complete with T100. Using ADP as the agonist, T100 produced a significant reduction in maximum platelet aggregation ($P<0{\cdot}01$), and disaggregation was achieved to a mean(s.d.) level of 48(13) per cent. Streptokinase did not produce any significant changes in any parameter of aggregation.

Keywords: Platelet aggregation, fibrinolytic agents, thrombolysis

Recombinant tissue plasminogen activator (rt-PA) has a high fibrinolytic activity[1,2] associated with a short half-life of <5 min[3,4]. It is relatively fibrin specific, activates fibrin-bound plasminogen to form plasmin, and does not significantly activate circulating plasminogen[5,6]. Experience with this agent for the treatment of peripheral arterial thrombosis is still limited[7–10] compared with that of low-dose streptokinase[11–19]. However, rethrombosis remains a problem with both agents; exposed endothelial collagen at the site of the thrombus causing procoagulant effects on the thrombus surface itself[20], residual thrombus[21–23], and direct activation of platelets and coagulation factors[24–27] may all play an important part. In coronary thrombolysis, rethrombosis rates of up to 45 per cent have been reported[28,29] Inadequate inflow and/or inadequate outflow cannot always be blamed and platelets are undoubtedly important in the pathogenesis of rethrombosis[30]. In coronary thrombolysis, the combination of streptokinase and aspirin has now been shown to be superior, in terms of the risk of mortality, to the use of either agent alone[31]. As yet there are no such similar studies in peripheral arterial thrombolysis. In peripheral limb arteries the volume and length of the occluding thrombus is many times greater than that in coronary thrombosis. The thrombi tend to be older and, therefore, more mature with greater cross-linking. Consequently thrombolysis takes longer. If there are significant differences in the effects of different thrombolytic agents on platelet function, this may be of considerable importance in determining the duration of lysis, the incidence of rethrombosis and the potential therapeutic benefit of concurrent administration of thrombolytic and antiplatelet agents.

We have therefore determined the effect of rt-PA and streptokinase on platelet aggregation Doses of rt-PA and streptokinase used in the experiments were based on the equivalent maximal concentration of each agent used in this centre for peripheral arterial thrombolysis

Method

Using no or minimal tourniquet time, 80 ml of blood were obtained from each of three healthy male volunteers Blood was collected into 0·109 M trisodium citrate at a ratio of 9.1. All samples were then centrifuged at 500*g* for 10 min. The supernatant platelet-rich plasma was pipetted off and platelet counts performed on a Coulter S Plus IV cell counter (Coulter Electronics Ltd., Luton, UK). The samples were centrifuged again at 2000*g* for 10 min to obtain platelet poor plasma. The platelet-rich plasma was diluted with platelet-poor plasma to a platelet count of 250×10^{9} ml^{-1}.

Threshold values for each of four agonists: thrombin (Diagnostic Reagents Ltd., Oxon, UK), collagen (Hormon-Chemie, Munich, GDR), adenosine diphosphate (ADP) and adrenaline (Sigma Chemical Company Ltd , Dorset, UK), were determined for each subject.

Plasma with a platelet count of 250×10^{9}/ml was stirred at 37°C with either saline or rt-PA (Boehringer Ingelheim, Bracknell, Berkshire, UK) at final concentrations of 10 (T10), 30 (T30) and 100 (T100) mg l^{-1}, with immediate addition of an agonist at the appropriate threshold value The same protocol was used for streptokinase (Streptase, Hoechst UK Ltd , Hounslow, UK), which was added to achieve final concentrations of 100 (S100), 300 (S300) and 1000 (S1000) units ml^{-1}. A Chronolog 440 dual channel aggrometer (Coulter Electronics Ltd., Harpenden, UK) was used at 37°C with the chart recorders set at 0·5 mm s^{-1}. Aggregation was measured from the change in light absorbance, represented in millimetres on the chart recorder. The rate of aggregation was calculated as half maximal aggregation (in millimetres) divided by the time taken to achieve half maximal aggregation (in seconds). After the lowest optical density had been reached, disaggregation was measured as the maximal increase in optical density and expressed as a percentage of the lowest optical density reached. In the case of curves that were non-reversible, maximal aggregation was taken as the aggregation present at 3 min (ADP, thrombin) or 4 min (collagen, adrenaline) after starting the experiment. The response to threshold doses was measured before and after each set of rt-PA or streptokinase concentrations was tested, and all experiments were performed at least in triplicate on prepared plasma from each of the three volunteers. Results are expressed as mean(s.d.). All statistics were performed using the Mann–Whitney *U* test.

Results

Tissue plasminogen activator

The effects of rt-PA on platelet aggregation are described in *Table 1*.

Collagen. A single experimental example is shown in *Figure 1*. Overall, rt-PA produced significant inhibition of the maximum extent of platelet aggregation induced by collagen at all doses used ($P<0{\cdot}05$ for T10 and T30, $P<0{\cdot}01$ for T100). The rate of aggregation was also significantly reduced by T100 ($P<0{\cdot}05$). No disaggregation occurred in either the presence or the absence of rt-PA.

Adrenaline An experimental example is shown in *Figure 2*. Overall, adrenaline-induced platelet aggregation was significantly inhibited ($P<0{\cdot}05$ for T10 and T30, $P<0{\cdot}01$ for T100). At a final dose of 100 mg l^{-1}, rt-PA produced significant disaggregation to a mean level of 26(11) per cent ($P<0{\cdot}01$).

Thrombin. An experimental example is shown in *Figure 3*. Overall, thrombin-stimulated platelet aggregation was significantly reduced by T100 ($P<0{\cdot}01$) and T30 ($P<0{\cdot}01$) only The rate of aggregation was also significantly reduced by T100 ($P<0{\cdot}05$) Disaggregation was dose-dependent with a mean level of 49(20) per cent with T30 ($P<0{\cdot}001$) and 146(34) per cent with T100 ($P<0{\cdot}001$).

Adenosine diphosphate An experimental example is shown in *Figure 4*. Overall, T100 produced a significant reduction in the rate ($P<0{\cdot}05$) and maximum platelet aggregation ($P<0{\cdot}01$) following addition of ADP. Disaggregation was consistently achieved only with T100, with a mean level of 48(13) per cent ($P<0{\cdot}001$).

Streptokinase

Streptokinase did not produce inhibition of either the rate of aggregation or the extent of aggregation, following the use of any of the four agonists in an analogous protocol

Discussion

Our results show that rt-PA can cause significant inhibition of platelet aggregation *in vitro*. The doses used in this study are based on the theoretical concentration of rt-PA or streptokinase delivered to an occluding thrombus using our standard protocol for local low-dose intra-arterial thrombolysis (33 mg l^{-1} rt-PA, 333 units ml^{-1} streptokinase).

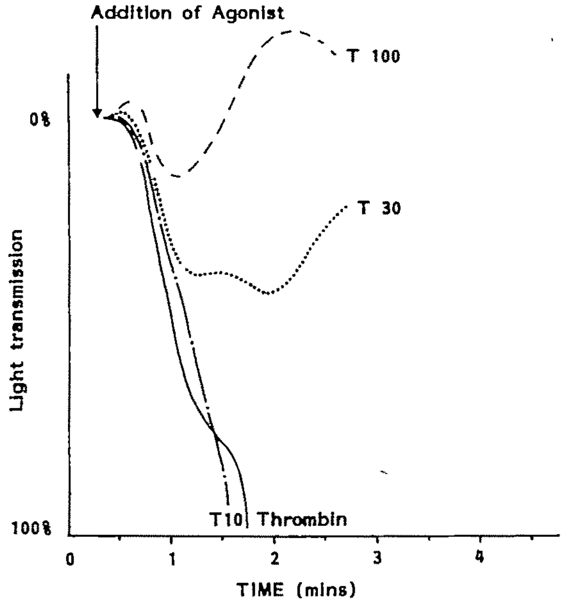

Figure 3 *Example of significant inhibition of platelet aggregation by 30 (T30) and 100 (T100) mg l^{-1} recombinant tissue plasminogen activator (rt-PA) following addition of thrombin (0·3 units final concentration). Disaggregation was seen following addition of 30 and 100 mg l^{-1} rt-PA*

A dose-dependent inhibition of collagen-induced platelet aggregation was produced by rt-PA, which was highly significant at the T100 concentration ($P<0{\cdot}01$). The rate of aggregation was also significantly reduced with rt-PA at this concentration ($P<0{\cdot}05$). No disaggregation was seen using the doses of rt-PA studied. In contrast, Loscalzo and Vaughan[32] found that collagen-induced platelet aggregation was resistant to rt-PA. This is because they were primarily studying the effects of rt-PA on disaggregation rather than inhibition of aggregation. In their protocol, rt-PA was added 1 min after the addition of agonist at a point where marked platelet aggregation had already occurred. Although our results demonstrate that rt-PA can significantly inhibit platelet aggregation induced by collagen, we agree that it cannot achieve disaggregation. The explanation of this phenomenon may be that platelets aggregate in response to collagen via fibrinogen-independent, as well as fibrinogen-dependent, mechanisms[33]. Platelets adhering to collagen release ADP, which promotes irreversible platelet aggregation.

Adrenaline-induced platelet aggregation was also significantly inhibited by all doses of rt-PA used. At the highest dose, disaggregation was seen to a mean level of 26(11) per cent.

Dose-dependent inhibition of platelet aggregation induced by thrombin was seen. rt-PA also produced dose-dependent disaggregation to a mean level of 146(34) per cent at the T100 concentration, suggesting that the final light transmission was actually lower than in the original sample. This may be due to disaggregation of previously formed platelet microaggregates, but this is only an hypothesis. These results verify the findings in earlier work[32]. The method of adding thrombin to platelet-rich plasma is not often used because of the difficulty in interpretation of the consequent increase in light transmission. This may be due to a combination of platelet aggregation and coagulation. However, using the same protocol with streptokinase, we did not see any significant effect on the rate or extent of aggregation using clinically equivalent doses, and so the effects seen can be attributed to rt-PA alone.

Only the highest concentration of rt-PA produced significant inhibition of platelet aggregation induced by ADP ($P<0{\cdot}01$). Loscalzo and Vaughan[32] found that rt-PA produced disaggregation when added to a suspension of ADP-aggregated platelets. This effect was dependent on dose and time. The earlier the rt-PA was added, the faster the rate of disaggregation and the greater its extent. The effect was inhibited by incubation of the platelet-rich plasma with α_2-antiplasmin before adding ADP. They concluded that disaggregation was the result of the proteolytic effect of plasmin and not the result of the amidolytic effect of rt-PA itself. Aspirin potentiated the effect on the rate of disaggregation over a wide range of rt-PA concentrations. Some disaggregation was seen[28] at concentrations of rt-PA as low as 5 mg l^{-1}. Whether local concentrations of rt-PA secreted by the vascular endothelium reach these levels is not known. It is unclear why rt-PA does not have such marked effects in our own study. In contrast, using New Zealand White rabbits, Ohlstein *et al.*[34] demonstrated that rt-PA at doses of 10 and 30 μg kg^{-1} min^{-1} produced *ex vivo* platelet hyperaggregability when collagen, arachidonic acid or ADP was used as the aggregating agent. These effects were apparently more pronounced at lower and subthreshold doses of collagen. Platelet counts were significantly decreased (by 16–22 per cent compared with control values). Streptokinase was also used in the same system: after a bolus dose of 40 000 units, a maintenance dose of 4000 units min^{-1} for 15 min was used. A similar platelet hyperaggregability was observed. The authors concluded that, following addition of rt-PA, platelet hyperaggregability was more common but of a shorter duration than following addition of streptokinase. The platelet hyperaggregation and thrombocytopenia observed in this study after systemic administration of rt-PA or streptokinase may be due to enhanced plasmin activity. Plasmin has a biphasic response, causing inhibition of platelet aggregation[35] and thromboxane B_2 production at low doses, but acting as a platelet agonist[36,37] at high doses. The doses used, 10 and 30 μg^{-1} kg^{-1} min^{-1}, are respectively equivalent to 42 and 126 mg h^{-1} for a 70 kg man. These are many orders of magnitude higher than those used in our own clinical study in humans and so direct comparison is not possible.

Although we have shown significant inhibition of platelet aggregation by rt-PA, we have shown neither inhibition nor enhancement of aggregation or of disaggregation by streptokinase. However, Fitzgerald *et al.*[25,38] have recently reported marked platelet activation following coronary thrombolysis with streptokinase. With additional *in vitro* tests they showed that the proaggregating effect was dose-dependent and seen over a range of 300–3000 units ml^{-1} with the maximum effect at 1883(440) units ml^{-1}. The mechanism of action is thought to involve plasminogen because, by passing citrated platelet-

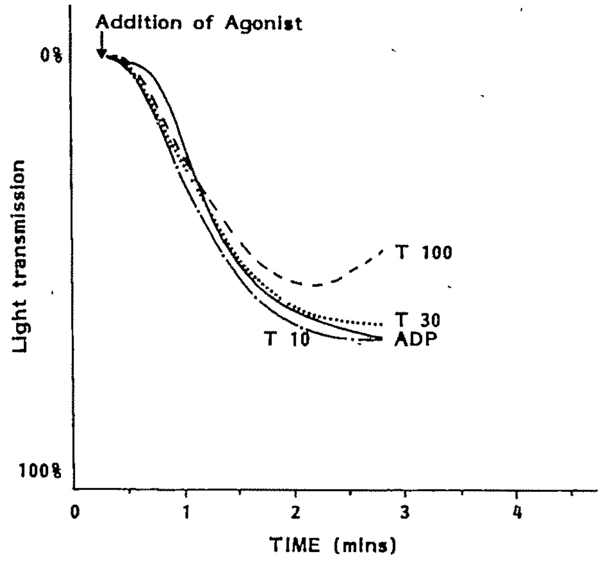

Figure 4 *Example showing that only 100 mg l^{-1} recombinant tissue plasminogen activator (T100) produced significant inhibition of maximal platelet aggregation and of the rate of aggregation following addition of adenosine diphosphate (2 µmol l^{-1} final concentration)*

rich plasma over a lysine–sepharose column to remove plasminogen, the proaggregatory effect of streptokinase (but not ADP) was prevented. The effect was subsequently restored by the addition of exogenous plasminogen. In contrast, after rt-PA therapy for myocardial infarction, platelet activity remains relatively unchanged[39]. Although our own study failed to demonstrate an enhancement of ADP-induced aggregation by streptokinase, we used a threshold dose of ADP, which was defined as the lowest concentration of ADP required to achieve progressive aggregation throughout the study period. In order to demonstrate similar enhancement of aggregation by streptokinase, we would need to repeat these experiments with lower doses of ADP to achieve minimal, reversible aggregation like Fitzgerald *et al.*[38]. It is also known that streptokinase can initiate specific antibody-mediated platelet aggregation *in vitro* and this may be associated with clot propagation and thromboembolism *in vivo*[40,41]. The extent of platelet aggregation induced by streptokinase correlates with the titre of antistreptococcal antibodies[42], which are present in up to 10 per cent of patients[43]. Antistreptococcal antibodies were not measured in our subjects; however, any potential augmentation of aggregation was not apparent at the doses of agonist used.

Various animal studies have also demonstrated that platelet activation does modify the response to streptokinase and other fibrinolytic agents[44,45]. Platelet aggregation is accompanied by platelet release reactions, which may have adverse physiological effects. The increase in biosynthesis of thromboxane A_2, a potent platelet agonist and vasoconstrictor[46], in Fitzgerald's study far exceeded the level in patients with unstable angina[47], in whom there is a beneficial effect of aspirin[48,49].

Various theories have been proposed to explain the platelet effects. Fibrinogenolysis will impair ADP-induced platelet aggregation as fibrinogen is a necessary cofactor[50]. Further impairment of aggregation and adhesion[51] is seen as a consequence of cleavage of glycoproteins Ib and IIb/IIIa (receptors for von Willebrand factor and fibrinogen respecspectively[52,53]), following activation of platelet-bound plasminogen[54]. Plasmin-induced cleavage of thrombospondin, fibronectin and fibrin can disrupt the matrix and result in platelet disaggregation[32]. This mechanism is enhanced by fibrinolytic agents, resulting in lysis of the fibrin framework that holds the platelets together.

The clinical importance of these enhanced platelet effects is uncertain. Groups of patients with thrombosis or at risk of thrombosis appear to have increased platelet adhesiveness[55], increased spontaneous aggregation[56], a reduced threshold to a range of agonists[57], and increased platelet release reactions[58]. However, although the mean values of all these parameters achieve significance for the groups as a whole, there is sufficient overlap with control populations to make their use in individual cases clinically unreliable. Nevertheless, an agent with platelet inhibitory rather than proaggregatory characteristics would appear highly desirable.

The concurrent use of an antiplatelet agent and a fibrinolytic agent may cause concern because of the potential bleeding complications. However, in the ISIS-2 study[31], although the combination of aspirin and streptokinase was associated with a 0·7 per cent increase in frequency of minor bleeds, no increase in major bleeds was noted and there was a 0·5 per cent reduction in the risk of stroke.

In our study rt-PA has been shown to have important dose-dependent inhibitory effects on all four platelet aggregation agonists assessed. Furthermore, using the same protocol with streptokinase, no significant inhibition of any parameter for any agonist is seen. These effects may help to explain the more rapid lysis seen with rt-PA in peripheral arterial thrombolysis compared with streptokinase[10], and may also help to reduce early rethrombosis. Concurrent therapy with antiplatelet agents may confer a greater effect with streptokinase than with rt-PA. Further *ex vivo* assessment of platelet behaviour using patients receiving peripheral arterial thrombolysis is required to substantiate these findings.

Subclavian aneurysm: a presentation of Takayasu's arteritis

A. W. Halliday, J. H. Horner* and A. O. Mansfield

*Department of Vascular Surgery, St. Mary's Hospital, London and * Department of Surgery, Ashford Hospital, Middlesex, UK*

Correspondence to: Miss A. W. Halliday, Department of Vascular Surgery, St. Mary's Hospital, London W2 1NY, UK

Takayasu's disease is a non-specific arteritis affecting the aorta and its major branches. It generally affects young women and is uncommon outside the Orient. We report an unusual case of this disease, presenting with an isolated aneurysm.

Case report

A 19-year-old woman presented with a painless lump in the right supraclavicular region and occasional tingling in the right hand. The lump was first noticed 6 months previously and had recently enlarged. There was no history of preceeding trauma. Her general health was excellent. She had been treated for pulmonary tuberculosis 11 years previously and at regular follow-up there were no signs of recurrent disease.

On examination she was apyrexial and normotensive. There was a diffuse 3 cm pulsatile swelling (with an associated loud bruit) in the right supraclavicular region, just lateral to sternomastoid and filling the supraclavicular fossa. Neurological examination of the right hand and arm was normal. There was no evidence of embolization.

A chest X-ray showed no signs of active tuberculosis. Haemoglobin, blood film, urea and electrolytes were normal. The erythrocyte sedimentation rate was not measured. Intravenous digital subtraction angiography demonstrated a saccular aneurysm arising from the proximal portion of the right subclavian artery (*Figure 1*). The aortic arch and its remaining branches except the right vertebral artery (which was not visualized) were normal. The aneurysm appeared much smaller than the clinical mass suggesting the presence of thrombus within it.

At operation, via transverse subclavicular and supraclavicular approaches, the aneurysm was exposed and dissected free of the phrenic nerve and brachial plexus. A 6 mm woven Dacron® (du Pont) graft was anastomosed end-to-side to the right common carotid artery. The subclavian artery was then ligated proximal to the aneurysm. The distal portion of the graft was anastomosed end-to-end to the axillary artery. The aneurysm was opened and feeding vessels were under-run from within the sac. Mural thrombus, aneurysm wall and adjacent macroscopically normal arterial wall were sent for culture and histological examination. The patient recovered uneventfully, and at follow-up 1 year later she was symptom-free and the graft was functioning well. Subsequent measurements of erythrocyte sedimentation rate were normal.

There was no evidence of tuberculosis on culture or histological examination. Sections of aneurysm wall showed lymphocytic and plasma-cell infiltration of the adventitia with a neutrophil vasculitis of the vasa vasorum. There was marked irregular loss of the elastic laminae and medial necrosis. No evidence of granulomata or Langhans' giant cells was found. Sections from the adjacent arterial wall were normal. From clinical and histological findings the pathologist diagnosed Takayasu's arteritis.

Discussion

The differential diagnosis in this case included atheroma, mycotic aneurysm, giant cell arteritis and Takayasu's disease. There was no evidence on enquiry or physical examination of significant atheromatous disease. Tuberculosis has long been recognized as an infrequent cause of arterial aneurysms, mainly affecting the aorta. Occasional cases of isolated subclavian aneurysm have been reported[1] associated with recently active pulmonary tuberculosis. In this country, tuberculosis is still quite common, while Takayasu's arteritis is rare. Most patients with Takayasu's are young Oriental females and in more than a quarter of cases there is a past history of tuberculosis[2]. General malaise, significant cardiac and pulmonary symptoms are found in about two-thirds of patients and these factors influence the natural history and prognosis[3]. Clinical differentiation between Takayasu's and giant cell arteritis may be difficult when there is an isolated aneurysm without occlusion. Vinijchaikul[4] reported eight cases of Takayasu's of which one presented in this way, but the most common presentation is of vessel occlusion.

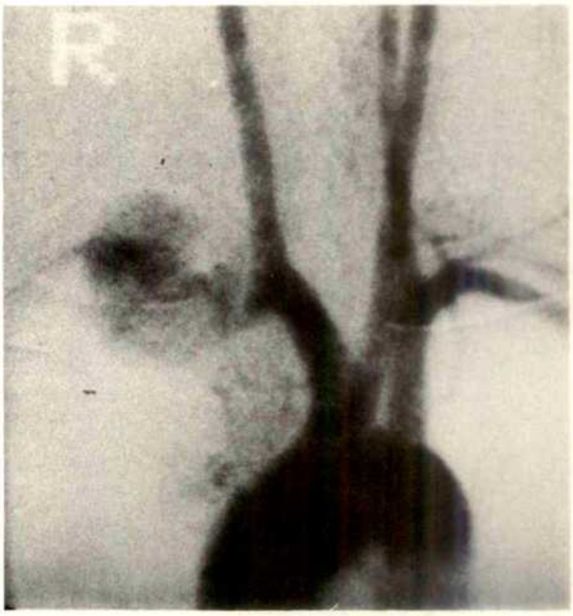

Figure 1 *Intravenous digital subtraction angiography of the aortic arch showing the right subclavian aneurysm*

The histological findings in this case are in keeping with those 'acute-stage lesions' described by Lagneau *et al.*[5], with a predominance of cellular infiltration, disruption of the external elastic lamina but preservation of the internal media. Although corticosteroids can produce dramatic symptomatic relief and may be of benefit in more advanced disease, there is little evidence to support their use in early isolated Takayasu's arteritis. The mortality rate within 2 years in recent reported series[2,3,4] varied between 7 and 16 per cent. Early treatment of the inflammatory process appeared to improve prognosis. Careful follow-up is the mainstay of treatment as surgery or corticosteroid therapy may be required to treat further manifestations of Takayasu's arteritis. With careful follow-up the prognosis in otherwise asymptomatic patients is excellent.

Electrocardiographic guided placement of central venous catheters

M. A. Hoffman, J. C. Langer, R. H. Pearl and R. M. Filler

Department of Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada
Correspondence to: Mr M. A. Hoffman, Department of Surgery, New England Medical Center, 750 Washington Street, Boston, Massachusetts 02111, USA

Central venous catheterization is commonly performed for both venous access and central venous pressure monitoring. Central venous access may be required for the administration of chemotherapeutic agents, parenteral nutrition, haemodialysis, plasmapheresis and plasma exchange. The large number of available devices for accessing the central venous circulation include silastic and polyethylene single and multilumen catheters, double lumen haemodialysis catheters, and venous access discs for subcutaneous implantation[1–4].

Standard placement techniques, whether by venous cutdown or percutaneous venepuncture, depend on radiological confirmation of catheter tip position by either fluoroscopy or static X-ray. While both methods are accurate and may produce hard copy documentation of catheter tip position, they are cumbersome, requiring specialized equipment and personnel.

We describe a technique for central venous catheterization based on electrocardiographic principles, first utilized for the placement of ventriculoatrial shunts[5,6]. This method uses the catheter, filled with a conducting medium, as an exploring electrode; the catheter tip position is judged by easily observable and reproducible P wave changes on an electrocardiographic monitor. The technique is simple and easily mastered, requires equipment routinely found in all operating theatres, and may be adapted to clinical settings outside the operating theatre. When performed properly, the method is accurate and reliable.

Surgical technique

Einthoven's triangle conceptualizes the body as a volume conductor, and describes the surface representation of cardiac electrical activity during the depolarization–repolarization process. Signal polarity depends on the orientation of the sensing electrodes and the vector of the cardiac electrical events[7]. When a transvenous probe is used as the negative lead, and the left leg position as the positive lead, positive deflections are encountered for the P waves, T waves, and QRS complexes when the heart is approached transvenously via the superior vena cava. *Figure 1* illustrates the changes in P wave configuration when a transvenous electrode as described passes through the superior vena cava, right atrium, and right ventricle.

This method utilizes the central venous catheter as the exploring transvenous electrode. Electrocardiographic leads are placed in the standard left and right upper and lower extremity positions and connected to an electrocardiographic oscilloscope. After the vein (the internal jugular, external jugular or cephalic) is exposed and controlled, the catheter tubing is tunnelled from the chest wall or subcutaneous pouch into the neck wound. The line is flushed with 0·9 per cent saline, and threaded through the venotomy for a distance of 4–6 cm. An 18 gauge needle is placed at the end of the catheter tubing, and the line is filled with 3 per cent saline. An insulated connecting wire (Medical

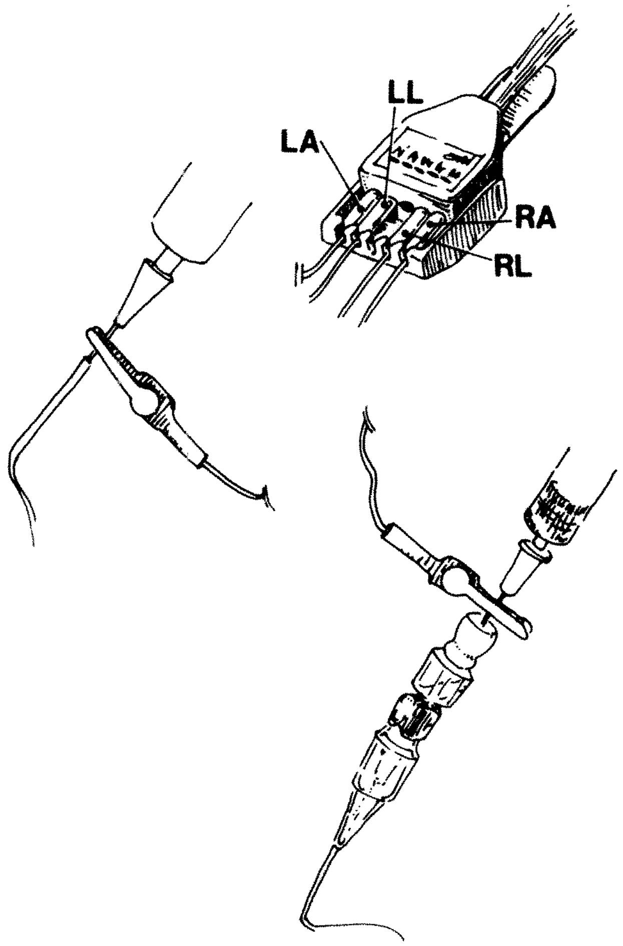

Figure 2 *Connecting cord. The alligator clip attaches to an 18 gauge needle, and the adaptor at the other end attaches to the left arm input station of the oscilloscope. Note that a blunt tipped 18 gauge needle is used when interfacing with venous access disc catheter tubing. A standard 18 gauge needle is passed through a rubber hub adaptor when silastic or polyethylene lines are utilized. LA, left arm; LL, left leg; RA, right arm; RL, right leg*

Engineering Department, Hospital for Sick Children, Toronto, Ontario, Canada) is attached to the metallic portion of the 18 gauge needle with an 'alligator' clip, and an appropriate electrical connector attaches the other end of the wire to the left arm input station of the electrocardiographic oscilloscope (*Figure 2*). The tracing is then observed on standard Lead III, noting the P wave configurational changes as the line is repositioned. The catheter is advanced slowly and, as the right atrium is entered, biphasic P waves are noted (*Figure 1*, B). The central venous line is withdrawn carefully. As the tip of the catheter moves from the right atrium into the superior vena cava, the P waves become monophasic, with spiked peaks (*Figure 1*, A). Further withdrawal dampens the P waves toward normal. The point at which the P wave first normalizes is the proper position of the catheter tip.

If no P wave changes are noted after a reasonable length of catheter has been advanced through the venotomy, the catheter has not entered the superior vena cava. The catheter is withdrawn back to the venotomy site, and further attempts to enter the central circulation are made. If P wave changes cannot be obtained after several efforts, a different venous route is chosen. Once proper placement is achieved, the catheter is secured and the neck incision closed.

Discussion

Experience of this technique of central venous catheterization has been obtained in over 400 neonates, infants and children, and in a prospective study in 50 consecutive patients the accuracy of electrocardiographic guided placement by subsequent chest X-ray[8] has been confirmed. Correct catheter position within the central venous circulation is invariably achieved when this method is properly executed. Conversely, the absence of P wave changes denotes improper positioning, and is a cause to abandon an unsuccessful route after multiple attempts.

While we do not routinely perform percutaneous central venous catheterization in infants and children, this technique can be easily adapted for this purpose, and a standard electrocardiograph machine may be substituted for the oscilloscope.

It has been our experience that patients with cardiac pacemakers or supraventricular dysrhythmias present a special problem, and in general, this technique cannot be used in this small group of patients. Fluoroscopic guide placement is the preferred method in this clinical setting.

We present a technique for central venous catheterization which utilizes the catheter as a probing electrode. The technique is accurate, can be easily mastered and taught to surgeons in training, uses equipment found in all operating theatres or accessible on most wards, and eliminates the need for X-ray to confirm catheter tip position.

The morbidity rate following 112 operations on the parotid gland is reported. Facial nerve palsy (temporary, 38 per cent; permanent, 9 per cent) and Frey's syndrome (11 per cent) were common following superficial parotidectomy. For pleomorphic adenoma and malignant lesions this procedure is justified. Benign conditions, which can be diagnosed preoperatively, should be treated by more limited surgery which has a lower complication rate.

Keywords: Parotidectomy, complications

Superficial parotidectomy has become the preferred method of treating space-occupying lesions of the parotid gland over the past 25 years[1,2] We have assessed the morbidity rate associated with this procedure over a 10-year period and compared it with that following local resection in lesions diagnosed preoperatively as benign by fine needle aspiration cytology (FNAC) – a technique we have previously reported[3].

Patients and methods

The records of 112 patients who had parotid gland masses operated on at Northwick Park Hospital (1977–87) and have been followed for a minimum of 12 months were reviewed retrospectively. Of these operations, 80 were performed by one consultant surgeon (A.E.K.) and ten by an experienced registrar (E.R.T C.O.) under the same consultant's supervision. The remaining procedures were done by another consultant. The operating registers and pathology records were carefully checked to ensure that all patients who underwent parotid surgery during this 10-year period were reviewed.

In all, 90 patients were contacted; 25 have been followed for 1–3 years, 25 for 3–5 years and 40 for more than 5 years Ten patients (9 per cent) died within 2 years of operation from unrelated causes and were free of recurrence at time of death. Twelve patients (11 per cent) were lost to follow-up. The commonest operation, carried out in 86 per cent (96 patients), was excision of the mass together with a surrounding rim of normal parotid tissue, i.e. superficial parotidectomy as described by Hobsley[4]. The remaining 14 per cent (16 patients) had limited surgery, i e. enucleation or excision biopsy, and this approach was adopted on the basis of a preoperative diagnosis of a benign lesion using FNAC.

Facial nerve damage was assessed according to the Chan and Gunn modification[5] of Patey's classification[6] in which grade III is a major weakness affecting all branches, grade II is moderate weakness affecting either eye or mouth, and grade Ib is minimal weakness at the angle of the mouth.

Results

The pathological findings consisted of benign lesions (59 cases, 53 per cent), pleomorphic adenoma (46 cases, 41 per cent) and malignant tumours (seven cases, 6 per cent). The benign lesions included 20 adenolymphomas, which thus comprised 18 per cent of all the cases or about 27 per cent of the tumours. The other benign lesions included enlarged lymph nodes, granulomas, tuberculomas and cysts.

The incidence of major complications according to pathology and type of operation is shown in *Table 1*. The complication rate in patients with benign pathology was the same as in those with pleomorphic adenomas and malignant tumours, whereas no significant complications occurred after limited surgery.

Facial nerve palsy occurred in 53 patients (47 per cent) (*Table 2*). Of ten patients with permanent palsy, six had deliberate sacrifice of a branch of the nerve as it passed directly into the tumour, and in the other four the tumour was situated deep to the facial nerve. In five of these the pathology was benign.

Frey's syndrome was seen in 12 patients, all following superficial parotidectomy. Six of these were severe and the other six were socially embarrassing. Half of these patients had benign pathology.

Spillage or incomplete excision occurred in 16 cases, six following superficial parotidectomy. One recurrence occurred 30 months after superficial parotidectomy, without spillage, for a pleomorphic adenoma. Minor complications included haematoma (16 per cent), temporary fistula (2 per cent), facial paraesthesia (32 per cent), painful neuroma (6 per cent) and keloid (3 per cent).

Discussion

Superficial parotidectomy for pleomorphic adenoma[1] has reduced the recurrence rate to less than 1 per cent[7]. This operation has significant complications.

Permanent facial nerve palsy

The reported incidence of permanent facial nerve palsy varies between 0 and 17 per cent[6–12] (9 per cent in this series). It occurs after all types of operation but in this report did not follow limited procedures. It is to be expected after deliberate sacrifice of a branch passing into a tumour, although this is not always the case.

Temporary facial nerve palsy

The reported incidence varies between 11 and 82 per cent[6–12] (38 per cent here, though no cases occurred after limited surgery). Normal function usually returns within 3–6 months, but it may take up to a year. It may be caused by nerve ischaemia, fatigue from excessive stimulation, stretching or haematoma formation[5]. The effects of this complication while it lasts are as devastating as a permanent palsy, and may cause depressive illness.

Frey's syndrome

The reported incidence varies between 2 and 43 per cent[6–12] (11 per cent here), but if the starch–iodine test is carried out it is almost always present to some degree[13,14]. It is seen only after superficial parotidectomy, as confirmed in this report. Although often dismissed lightly, the extent of the social incapacity ranges from regular mopping during eating to a virtually housebound existence.

The most significant finding is the number of major complications in the 59 patients with quite innocent pathology: 8 per cent permanent palsy, 36 per cent temporary palsy and 10 per cent Frey's syndrome. All of these complications followed superficial parotidectomy (48 patients). None occurred after limited surgery. When the latter is combined with radiotherapy,

Values in parentheses are percentages

however, permanent and temporary palsy have been reported[15,16].

Benign lesions require only enucleation. Such limited surgery does reduce complications. The selection of cases for a conservative approach requires a reliable method of preoperative diagnosis. We have previously reported the role of FNAC and computed tomography in the management of parotid swellings[3,17]. Aspiration cytology has a predictive accuracy of more than 95 per cent[3,17–22]. Many of the cases in this series were not assessed by FNAC. This has become part of our standard practice only recently, and the accuracy of FNAC cannot therefore be assessed from this study. Despite fears of tumour dissemination by this technique, no case of tumour seeding has been reported using a fine needle with a single pass technique. We do not routinely excise the needle track as it is usually difficult or impossible to identify. Careful follow-up is required to confirm that the long-term risk of implantation is negligible. In our experience aspiration cytology has provided, in every case, the distinction between benign lesions and pleomorphic adenoma.

The surgical removal of a parotid tumour should be planned on the basis of preoperative cytological diagnosis to enable surgery to be tailored appropriately and so reduce the complications of unnecessarily extensive procedures.

Correspondence to.
Mr J. R Anderson

We have evaluated the sensitivity, specificity and accuracy of laparoscopy under general anaesthesia, ultrasound and computed tomography (CT) in detecting intra-abdominal metastases in 90 consecutive patients with carcinoma of the oesophagus or cardia. Metastases were histologically confirmed as hepatic in 25 patients, nodal in 35 and peritoneal in nine. All investigations had high specificity (86–100 per cent) for each type of metastasis. Laparoscopy was found to be significantly more sensitive ($P<0.01$; $P<0.02$) *and more accurate* ($P<0.01$; $P<0.01$) *than either ultrasound or CT, respectively, with regard to hepatic status. Although laparoscopy performed best with regard to nodal metastases, this reached statistical significance only when sensitivity of ultrasound was compared* ($P<0.01$)*. Neither ultrasound nor CT detected any peritoneal metastases, although laparoscopy detected eight out of nine, giving a sensitivity of 89 per cent and an accuracy of 98 per cent. There was no morbidity or mortality associated with laparoscopy, which offers a safe, reliable method of determining intra-abdominal status and may obviate the need for surgery in some patients with malignant dysphagia.*

Keywords: Carcinoma of oesophagus or cardia, intra-abdominal metastases, laparoscopy, ultrasound, computed tomography, accuracy

Squamous carcinoma of the oesophagus and adenocarcinoma of the cardia, although biologically different tumours, have a number of common features. Both are associated with distressing dysphagia, resection carries a high level of operative risk, and prognosis is poor, especially in the presence of disseminated disease. It is now possible to achieve adequate palliation of malignant dysphagia in patients with widespread disease, or who are unfit for major surgery, by a variety of non-operative methods. The accurate and reliable detection of intra-abdominal metastatic disease is therefore of considerable importance if needless surgery is to be avoided.

Hepatic metastases are usually associated with a poor prognosis, and knowledge of their presence or absence has a significant bearing on therapeutic decisions in a variety of malignant diseases. Various methods for the preoperative detection of hepatic metastases have been assessed, including biochemical tests of liver function, isotope liver scanning and, more recently, ultrasound scanning and computed tomography (CT). All of these methods have limitations and drawbacks, not least of which, particularly regarding CT, may be availability and cost. There is little information regarding the effectiveness of these non-invasive tests in detecting other intra-abdominal metastases, particularly peritoneal or nodal metastases, which may also have an influence on therapeutic options.

Laparoscopy has been evaluated in the assessment of intra-abdominal dissemination in patients with gastric[1,2], pancreatic[3], biliary[4,5] and a number of non-gastrointestinal malignancies[6–10]. There are few studies on the role of laparoscopy in the preoperative assessment of patients with dysphagia due to carcinoma of the oesophagus or cardia. A prospective, comparative evaluation of the accuracy of laparoscopy, ultrasound and CT in detecting intra-abdominal metastases in patients with carcinoma of the oesophagus and adenocarcinoma of the cardia is presented.

Patients and methods

Between February 1986 and October 1988, 90 consecutive patients with dysphagia were studied. All had biopsy-proven carcinoma of the oesphagus or cardia but patients with extensive proximal gastric cancer involving the cardia were not included. All patients underwent abdominal ultrasound using an Advanced Technology Laboratories (Washington, UK) real-time ultrasound scanner fitted with a 3·5 MHz transducer, contrast enhanced CT using an EMI model 5005 whole body scanner (EMI Ltd, Hayes, UK) and laparoscopy. Laparoscopy was carried out under general anaesthesia with intermittent positive pressure ventilation. An Olympus® (Keymed, Southend, UK) oblique viewing laparoscope was used with an Eder Insumat Insufflator® (Down Surgical Ltd., Mitcham, UK). The laparoscope was usually inserted subumbilically and when indicated a liver biopsy was obtained with a Tru-Cut® (Travenol Laboratories Incorporated, Deerfield, Illinois, USA) biopsy needle under direct vision. Instruments for laparoscopic manipulation and punch biopsy were not available. Each investigation was carried out by a single investigator without prior knowledge of the results of the other two investigations. However, the results of all three investigations were collated along with other pertinent data when decisions regarding individual patient management were made.

Intra-abdominal metastases were considered to be proved only when histological confirmation was obtained either by laparotomy and biopsy, or by laparoscopy and biopsy and, on occasion, by autopsy findings.

The sensitivity, specificity and accuracy of each technique was calculated using the decision matrix and formulae of McNeil and Adelstein[11]. Thus the sensitivity of each investigation is the proportion

Values in parentheses are percentages

of positive tests in all patients with proven disease; the specificity is the proportion of negative tests in all patients proved not to have disease, and the accuracy is the ratio of correct results (true positive + true negative) to the total number of tests. The statistical difference between tests was calculated using a χ^2 test with Yates' correction.

Results

There were 55 men and 35 women aged 40–93 years with a mean(s.d.) age of 64(11·7) years. Of 36 cases of squamous carcinoma, 11 involved the upper third of the oesophagus, 19 the middle third, and six the lower third. In 54 cases of adenocarcinoma, 45 involved the cardia but were mainly in the oesophagus rather than stomach, and nine were confined to the oesophagus – three in the upper and six in the middle third (*Table 1*).

Laparotomy was performed on 65 patients, of whom 38 had resection of the primary tumour. Of the 27 patients not having resection of the tumour, 15 had Celestin® (Ambleletin Ltd., Gloucester, UK) intubation either as a planned primary procedure (eight cases) or because of failure to pass a guide-wire at attempted endoscopic intubation (seven cases). Twelve patients were found to have advanced disease at laparotomy, three of whom were managed by Atkinson intubation, eight by laser therapy and one by chemotherapy. No surgery was performed in 25 cases, either because widespread metastatic disease was proved (20 cases) or because they were considered unfit for major surgery (five cases). Twelve were managed by pulsion intubation, 11 by laser therapy and two by radiotherapy.

The number, distribution and origin of intra-abdominal metastases are presented in *Table 2*. Intra-abdominal metastases were present in 20 (51 per cent) of the 39 patients with upper or middle third lesions and in 30 (59 per cent) of the 51 patients with lower third or cardia lesions.

There was a total of 25 patients with hepatic metastases that were confirmed histologically either by laparotomy and biopsy or by laparoscopy and percutaneous biopsy under direct vision. None of these patients had hepatomegaly or abnormal liver function tests. Of these, 17 (68 per cent) were in patients with primary adenocarcinoma and eight (32 per cent) in patients with squamous carcinoma. Seven (28 per cent) occurred in association with upper or middle third lesions and 18 (72 per cent) in association with lesions of the lower third of the oesophagus or cardia.

Thirty-five patients had nodal metastases proved by laparotomy and subsequent histology. Twenty-two (63 per cent) of these were in patients with adenocarcinoma and 13 (37 per cent) in those with squamous carcinoma. Sixteen (46 per cent) nodal metastases were associated with upper or middle third lesions and 19 (54 per cent) with lower third lesions or lesions of the cardia. Nine patients had peritoneal metastases proved at laparotomy: five (56 per cent) in patients with adenocarcinoma, four (44 per cent) in those with squamous primaries; four (44 per cent) in association with upper or middle third lesions and five (56 per cent) in association with lower third or cardia lesions.

As hepatic metastases could be confirmed histologically without laparotomy, all 90 patients investigated were used in the calculation of sensitivity, specificity and accuracy of the three investigative modalities. However, as peritoneal and nodal metastases were confirmed by histology only after laparotomy, only the 65 patients undergoing surgery were considered when calculating the sensitivity, specificity and accuracy of the investigative modalities in detecting these metastases.

Laparoscopy correctly identified 22 of the hepatic metastases with three false negatives and no false positives, giving a sensitivity of 88 per cent, a specificity of 100 per cent and an overall accuracy of 96 per cent (*Table 3*). Of the three false negatives, two were due to failure to visualize one or other lobe of the liver owing to intra-abdominal adhesions as a result of previous surgery and one was due to the posterior location of metastatic deposits. Ultrasound identified 12 of the hepatic metastases, with 13 false negatives and two false positives, giving a sensitivity of 48 per cent, a specificity of 97 per cent and an accuracy of 83 per cent. CT identified 14 hepatic metastases with 11 false negatives and two false positives giving a sensitivity of 56 per cent, a specificity of 97 per cent and an accuracy of 85 per cent. Laparoscopy was significantly more sensitive than either ultrasound ($\chi^2=9·191$, $P<0·01$) or CT scan ($\chi^2=6·349$, $P<0·02$) in detecting hepatic metastases and was also more accurate ($\chi^2=8·889$, $P<0·01$ and $\chi^2=6·859$, $P<0·01$, respectively) than both scanning techniques. There were no statistical differences between ultrasound and CT in detecting hepatic metastases. Twelve of the hepatic metastases were detected by all three tests and two by laparoscopy and CT. Three were missed by all three tests and eight were detected only by laparoscopy. The false positive results of ultrasound and CT were in four different patients and subsequent follow-up by repeat computed tomographic scan failed to show the

Histologically proven, $n=9$; confirmed absent, $n=56$

development of metastatic deposits which might have indicated detection of occult hepatic metastases at first investigation.

Peritoneal and nodal metastases were only confirmed histologically if laparotomy was performed. Of the 65 patients having surgery, 35 had histologically confirmed intra-abdominal nodal metastases (*Table 4*). In 21 of these patients (60 per cent) the nodes involved were around the coeliac axis. Laparoscopy identified 18 of the 35 with 17 false negatives and one false positive. Ultrasound detected only six, with 29 false negatives and two false positives; CT detected 11 with 24 false negatives and four false positives. The sensitivities were therefore 51, 17 and 31 per cent, the specificities 97, 93 and 87 per cent, and the overall accuracies 72, 52 and 57 per cent for laparoscopy, ultrasound and CT, respectively. Laparoscopy was statistically more sensitive ($\chi^2=9\cdot130$, $P<0\cdot01$) and more accurate ($\chi^2=5\cdot535$, $P<0\cdot05$) than ultrasound in detecting nodal metastases. The differences between laparoscopy and CT, however, although favouring laparoscopy, just failed to reach statistical significance at the 5 per cent level ($\chi^2=3\cdot618$ and $\chi^2=3\cdot364$, $P>0\cdot05$). There were no differences between ultrasound and CT in the sensitivity or accuracy in detecting nodal metastases.

Nine patients had peritoneal metastases proved at laparotomy (*Table 5*). Of these, eight were correctly identified before operation by laparoscopy with no false positives and one false negative in a patient with metastatic deposit on the inferior surface of the transverse mesocolon. The sensitivity of laparoscopy was 89 per cent, the specificity 100 per cent and the accuracy 98 per cent. Ultrasound demonstrated free intra-abdominal fluid in two patients but no definite metastatic deposits, and CT failed to detect any of the peritoneal metastases.

There was no morbidity or mortality associated with laparoscopy

Discussion

The accurate assessment of intra-abdominal dissemination of malignancy is of considerable importance both in tumour staging and in planning therapeutic strategies. Over the years a great deal of attention has been given to the preoperative detection of hepatic metastases. Biochemical tests of liver function including serum levels of alkaline phosphatase, transaminases and γ-glutamyl transferase are relatively easy to perform and with increasing automation have become widely available. However, their role in the accurate assessment of liver metastases would seem to be limited[13–15].

The results of isotope scanning for detecting liver metastases are rather conflicting. Lamb and Taylor[16] in 1982 found that both liver scintiscans using technetium–sulphur colloid and ultrasound were 97 per cent accurate in determining the presence or absence of liver metastases in 100 patients with colorectal cancer of whom 15 had proven hepatic metastases. Most other authors, however, have reported accuracies of the order of 64–80 per cent for hepatic scintiscans[8,17–19].

Ultrasound scanning, and particularly grey scale ultrasound, has become increasingly available and when used to enhance the diagnostic accuracy of scintiscans has been shown by Sullivan *et al.*[20] to have an accuracy of 93 per cent. Apart from Lamb and Taylor[16], who showed a 97 per cent accuracy, other authors have not been able to reproduce this level of accuracy, but figures of 75–80 per cent have been reported[1,15,17].

It was thought, with the advent of CT, that other scanning techniques might be superseded but several studies have demonstrated that overall accuracy in determining the existence of hepatic metastases is still only in the order of 80–85 per cent[15,17]. Smith*et al.*[17] compared the accuracy of scintiscan, ultrasound and CT in patients with a variety of primary tumours with potential hepatic involvement and found little difference in accuracy in the three techniques, with scintiscans and ultrasound both 80 per cent, and CT 84 per cent accurate. They concluded that lesions <3 cm in diameter were liable to be missed by all three techniques and that direct visualization and biopsy were the only means of making a definitive diagnosis of hepatic metastases. Kemeny *et al.*[15] found a sensitivity of 87 per cent for CT combined with carcinoembryonic antigen levels, but overall accuracy was only 64 per cent for this combined method of assessment.

Scanning techniques are highly dependent on the availability of sophisticated equipment and experienced observers to operate them. Both ultrasound and CT are still evolving and it could be expected that accuracy will steadily increase. However, it is unrealistic for every unit to be abreast of the latest developments of scanning technology and accuracy is still dependent to a great extent on the skill and experience of the observer using the equipment. Neither biochemical tests nor scanning techniques address the problem of other intra-abdominal metastases, particularly peritoneal seeding.

Laparoscopy is widely used as a diagnostic and therapeutic tool in gynaecology, but is relatively little used in general surgery. Its value has been assessed in a number of clinical areas, including the staging of primary intra-abdominal tumours, the evaluation of metastatic disease, and the diagnosis of jaundice and abdominal pain. Complications under either local or general anaesthesia have been few[1,4,5,9] and diagnostic accuracy has been high. Although it has been found to be of little value in the diagnosis of unexplained abdominal pain[5,7,9], it has contributed to the elucidation of the cause of jaundice[4,5,7] where other less invasive tests have not been diagnostic. The staging of pancreatic and other intra-abdominal tumours has been improved using laparoscopy[3,10], and accurate evaluation of the condition of the liver in patients with primary bronchial, breast and lymphoid tumours has been well documented[6,8]. One of the major benefits of laparoscopy has been the opportunity to obtain tissue samples accurately under direct vision not only from the liver but also from nodal or peritoneal metastases, often confirming or refuting the results of other non-invasive investigations. It has also been found to be useful in evaluating the stage of tumours amenable to treatment by chemotherapy or radiotherapy, e.g. lymphomas and ovarian or other gynaecological malignancies[8].

Laparoscopy has been evaluated in the management of patients with gastric cancer with somewhat conflicting results. Shandall and Johnson[1] found laparoscopy of doubtful value in patients with gastric cancer because a high proportion required palliative surgery, whereas Gross *et al.*[2] found it beneficial in avoiding unnecessary surgery. Clearly the location of the primary lesion and the patient's symptoms are important in that those with distal lesions causing pyloric obstruction and vomiting may well require palliative gastroenterostomy whereas those with proximal lesions and dysphagia may not benefit from surgery but may be palliated by non-operative methods.

Few studies have evaluated laparoscopy in relation to tumours of the oesophagus or cardia[1,12] and there are no comparative studies of ultrasound, CT and laparoscopy in evaluating this group of patients.

In our study the results of ultrasound and CT in determining liver status were similar to those reported by others, with overall accuracies of 83 and 85 per cent, respectively. Laparoscopy performed significantly better, with an overall accuracy of 96 per cent, was associated with no mortality or morbidity and allowed histological confirmation of metastases. The three false negative results with laparoscopy were caused by intra-abdominal adhesions in two cases and the posterior location of metastases in one case. Although it is conceivable that some of these technical problems could be overcome by manoeuvres such as inserting the laparoscope in different quadrants of the abdomen, or using instruments to break down adhesions, we must accept that there will be a failure rate for laparoscopy as well as for scanning techniques. It is of note that the metastases in these three cases were also missed by both ultrasound and CT. Of the 25 hepatic metastases, 12 were detected by all three modalities. CT and ultrasound have equally high specificity (97 per cent); therefore positive results can be relied upon. Laparoscopy is probably not required in this situation unless histological confirmation of metastases is desired. CT detected two more patients with hepatic metastases than ultrasound, and may therefore have a slight advantage. However, this is probably offset by the increased cost of the investigation. As eight patients with negative ultrasound and CT were found to have hepatic metastases at laparoscopy (i.e. 32 per cent of all proven hepatic metastases) this is clearly a useful additional investigation if either of these scanning techniques is reported as negative.

Ultrasound and CT perform poorly with regard to nodal metastases, but laparoscopy was not significantly superior to CT although it was significantly better than ultrasound. Metastatic deposits may often be present in nodes that are only slightly if at all enlarged and may therefore not be visible on scan at the present limits of resolution. It may be possible to identify smaller nodes at laparoscopy, but they may or may not contain tumour and a significant proportion may be located only around the coeliac axis and therefore may not be visible by standard laparoscopic techniques. On the whole, nodal metastases are of lesser importance in determining resectability of tumours of the oesophagus or cardia compared with liver metastases or peritoneal metastases, but knowledge of their status may be of importance in staging of disease in patients who are refused surgery on other grounds.

Peritoneal metastases, however, are of considerable importance as their presence will usually preclude major resectional surgery. Although ultrasound demonstrated free peritoneal fluid in two cases, neither ultrasound nor CT demonstrated any of the peritoneal metastases in nine patients. Laparoscopy was positive in eight of these nine patients. Had punch biopsy been available histological proof could have been obtained, but some of these patients required laparotomy for Celestin intubation. The lesions missed in the final patient were located on the inferior surface of the transverse mesocolon. This area is not visualized by standard laparoscopic techniques but may be seen using the techniques described by Cuschieri and Berci[21].

It is worthy of note that 51 per cent of the patients with upper and middle third lesions had intra-abdominal metastases, a figure similar to the 58 per cent of patients with lower third or cardia lesions. It is clearly worth pursuing intra-abdominal dissemination even in patients with lesions high in the oesophagus if unnecessary surgery is to be avoided. The high incidence of metastatic disease in the present group of patients reflects the availability of palliative techniques in this unit and therefore influences the referral practice.

In patients with carcinoma of the oesophagus or cardia laparoscopy offers an accurate, reliable and safe method of preoperative assessment. We would hope that by using laparoscopy in conjunction with the non-operative methods of palliation, unnecessary surgery could be avoided in a significant proportion of patients with malignant dysphagia.

Cryotherapy for liver metastases: a new approach

R. M. Charnley,
J. Doran and
D. L. Morris

Mr D. L. Morris

A new system designed for cryosurgery of liver metastases is described. The cryoprobe, which utilizes circulating liquid nitrogen and produces a spherical iceball around each metastasis, is controlled by operative ultrasound. There was nor mortality and all patients left hospital within 10 days. Cryotherapy produced an area of destruction within the liver substance which decreased in size by 6 weeks as shown on serial computed tomographic scanning.

Keywords: Hepatic metastases, cryosurgery, intraoperative ultrasound

Cryotherapy has been used for the treatment of many benign and malignant conditions[1]. Neoplasms of the skin, rectum, bone and larynx have been successfully treated[2–5]. Cryotherapy has also been used for the treatment of liver tumours but using techniques which result in the destruction of a large amount of surrounding liver parenchyma[6,7]. We have designed a system which uses a new type of cryoprobe enabling the freezing of intrahepatic lesions to be performed with only the destruction of a small rim of normal liver tissue around each lesion.

Patients and methods

Seven patients (median age 56 years, range 46–61 years) with liver metastases (six from colorectal cancer, one from carcinoid) have undergone hepatic cryotherapy using a newly designed cryoprobe with an insulated 5 mm diameter shaft (Cryogenic Technology Ltd., Ripley, UK). Within the tip of the probe liquid nitrogen is circulated at −196°C. In each patient the liver was mobilized at laparotomy and following bimanual palpation intraoperative ultrasound was performed using a Bruel and Kjaer (Nærum, Denmark) ultrasound apparatus 1846 and intraoperative ultrasound probe 8537 which incorporates a 7 MHz transducer.

The tip of the probe was passed into the centre of each metastasis using intraoperative ultrasound to localize impalpable lesions (*Figure 1*). The frozen area or iceball created was easily imaged by intraoperative ultrasound, appearing as a dark (hypoechoic) area (*Figure 2*), the size of which could be monitored. Freezing was continued until the diameter of the iceball was 1 cm greater than that of the metastasis. Thawing was then commenced by circulating nitrogen at room temperature down the probe and after several minutes the probe could be removed from the frozen metastasis. The track was packed with oxidized cellulose to prevent bleeding. Prophylactic antibiotics were given to all patients. Postoperative computed tomographic (CT) scans were performed on all patients and they were observed closely in the outpatient department for adverse effects of the treatment.

Results

Thirty-nine metastases were identified in the seven patients (range 3–12 metastases per patient). Eight metastases were impalpable and only detected by intraoperative ultrasound. The diameter of lesions ranged from 0·3 cm to 6·5 cm and the time for freezing from 1 min to 36 min.

All patients made an uncomplicated postoperative recovery and were discharged home 7–10 days after surgery. The effect of this treatment was monitored by CT scan. *Figure 3* shows one impalpable metastasis before operation, 3 days after operation and 6 weeks after operation. Cryotherapy produced an area of destruction within the liver substance which often contained some gas from tissue necrosis (*Figure 3***b**). After 6 weeks this area of necrosis had decreased in size.

No adverse effects have been observed during the follow-up period which ranges from 1 to 6 months. The patient with carcinoid has had total relief from his symptoms of flushing and diarrhoea. Of the patients with colorectal metastases, four have been followed up for more than 3 months. In three patients serum carcinoembryonic antigen concentrations fell following cryotherapy and in one of them serum carcinoembryonic antigen had fallen from 4·6 μg/l before cryotherapy to < 1·5 μg/l 2 months later. However, it is too early to comment on the actual benefit derived by these patients.

Discussion

The safety and benefit of hepatic resection for patients with less than four unilobar metastases from colorectal cancer are well established. An acceptable operative mortality rate for major resection of about 5 per cent is expected, and up to 35 per cent

of patients undergoing successful resection can expect to live 5 years[8]. For patients with unresectable disease systemic chemotherapy has proved to be disappointing and regional chemotherapy, although producing response rates of 70 per cent in some centres, is accompanied by an unacceptable level of serious complications in most series[9,10].

Cryosurgery is an established technique for the treatment of many benign and malignant lesions[1–5]. Previous attempts at cryosurgery for hepatic malignancy have involved the use of either a surface probe with a central spike down which cold is conducted so producing at best a cone shape of liver destruction, or surface application of a hollow plate-like probe which is only suitable for the destruction of superficial lesions. Using these techniques, impressive results for hepatic cryosurgery have been described[6,7]. The circulating liquid nitrogen probe which we have used has the advantage of delivering a temperature of −196°C to the lesion with destruction of only a rim of normal liver tissue around each lesion.

The technique of intraoperative ultrasound allows the detection of more metastases than is possible using conventional abdominal ultrasound or CT scanning[11] and also allows localization of lesions to be carried out at laparotomy. Impalpable lesions as small as 5 mm in diameter may be detected. These small impalpable metastases often make a patient's disease unresectable. In such a case, cryosurgery using the circulating liquid nitrogen probe has the potential to destroy all detectable metastases, with minimal destruction of surrounding hepatic parenchyma. In addition it has been demonstrated previously that large blood vessels tolerate freezing extremely well because the passage of warm blood causes dissipation of the freezing process so reducing tissue damage close to the vessel wall[12]. Cryosurgery, therefore, may be able to destroy lesions that have been deemed to be unresectable because of their proximity to large veins.

It is acknowledged that the effect on survival of patients treated by cryotherapy using this new system has not yet been studied but this treatment is easily performed, is well tolerated and certainly produces radiological evidence of necrosis. Its role in palliation and possible improvement in survival time clearly requires investigation.

Acknowledgements

We are grateful to Mr Brian Clarke and Mr Philip Shepherd of Cryogenic Technology Ltd. who have co-operated with us in developing the cryoprobe.

Resectability of large focal liver lesions

Despite modern imaging techniques evaluation of the resectability of large focal liver lesions is often difficult or impossible until the time of operation. Based on experience with 54 primary or secondary focal liver tumours, a simple morphological classification has been found to be reasonably predictive of resectability. All tumours were classified before operation using computed tomography, ultrasound and angiography; 38 patients underwent laparotomy. Dependent, 'hanging' tumours (n = 7) were resected in six cases, expansively growing 'pushing' tumours (n = 19) were resected in 18 cases, and infiltrating, 'invasive' tumours (n = 17) were not resected because of involvement with major vascular structures. Eleven small tumours (< 5 cm) were not classifiable by this system. This simple classification may be a useful clinical concept in preoperative assessment of resectability of focal liver lesions. Hanging tumours should always be resected, and large expansile tumours are generally resectable despite their size. Invasive tumours can only be resected in exceptional cases.

Preoperative assessment of resectability in large focal primary or secondary benign or malignant liver tumours remains a difficult challenge. The actual resectability rate depends on the skill and experience of the individual surgeon and on referral patterns in specialized hepatobiliary clinics. In general, few liver malignancies are resectable. For example, only 5 per cent of hepatic metastases from colorectal cancer have been found to be resectable[1] and nearly 50 per cent of patients specifically referred for hepatic resection to hepatobiliary clinics will not come to actual resection[2]. However, the widely accepted criteria of irresectability such as bilobar involvement, vessel infiltration and very large tumour size are no longer unquestioned. In particular, tumour size alone does not appear to be a contraindication to hepatic resection[3–9].

Standard imaging techniques provide valuable and detailed information about the resectability of large focal malignant or benign tumours. Despite increasingly refined methods of computed tomography, ultrasonography, hepatic angiography, late phase portography and inferior cavography, definitive preoperative evaluation of resectability in large lesions with involvement of the hilus or of the retrohepatic vena cava is difficult or impossible, and the question of resectability often remains open until the time of surgery.

This study investigates a simple clinical concept of tumour morphology in the preoperative assessment of focal liver lesions. Based on clinical experience and observation of a large number of liver lesions, a simple classification is proposed which has been found to be useful in the preoperative assessment of large focal liver tumours.

Materials and methods

Three different morphological varieties of tumour are defined as follows.

'Hanging' tumours

These tumours grow with a base adjacent to the free liver edge and hang in their entirety, or at least their major part, free of the rest of the surrounding liver tissue in the abdominal cavity. Some of these tumours can be literally pedunculated[10]. *Figures 1* and *2* demonstrate a typical hanging tumour.

'Pushing' tumours

These tumours grow expansively and compress the surrounding normal liver tissue. Even in malignant tumours there is usually a rim of compressed atrophic liver parenchyma forming a pseudocapsule or at least a well-defined plane between the malignant and the surrounding benign tissue. The pushing tumours can grow to be very large, involving nearly the whole liver (*Figures 3* and *4*).

'Invasive' tumours

These tumours, which can be very large, grow without anatomical limits and no clear margin or rim of compressed pseudocapsule is formed so that differentiation of normal from malignant areas of the liver is difficult (*Figure 5*).

Small tumours, < 5 cm in diameter, cannot be properly classified within this system because they do not display gross morphological differences.

We have investigated prospectively the resectability of all liver tumours referred to our clinic from October 1986 to September 1988. All primary benign or malignant focal tumours and liver metastases excluding haemangioma were considered. The tumours were preoperatively classified by the senior surgeon and radiologist generally on the basis of a computed tomographic scan and an angiogram. A total of 54 primary or secondary focal liver tumours (*Table 1*) were assessed by imaging techniques (ultrasonography, computed tomography, angiography, late phase portography or inferior vena cavography). According to the preoperative clinical classification in these 54 patients, we identified 19 pushing, seven hanging, 17 invasive, and 11 tumours too small to be classified. Of these, 37 lesions were considered resectable

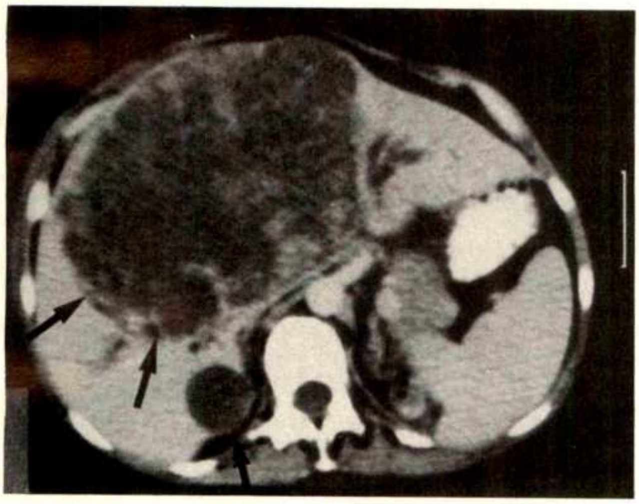

Figure 3 *'Pushing' tumour: metastasis of a hypernephroma in a 33-year-old woman. This is a typical example of a well defined malignant lesion occupying almost the entire liver (arrows) apart from the posterior sector of the right side. The tumour was resected by extended left hepatectomy; the patient is alive 2 years later*

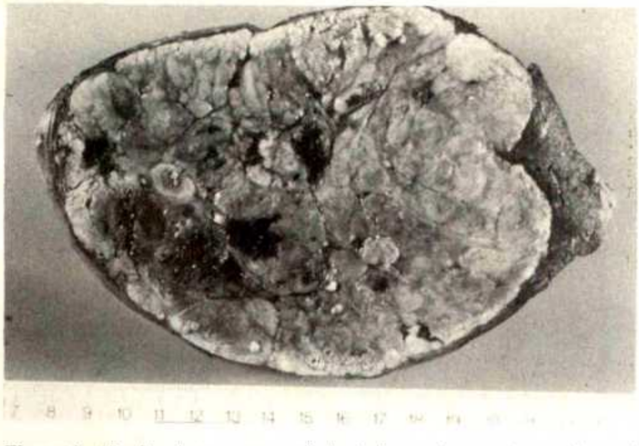

Figure 4 *'Pushing' tumour: pathological specimen of a colorectal metastasis in the liver of a 51-year-old man. The small frame of compressed liver tissue forms a pseudocapsule*

and the patients underwent laparotomy. An additional patient underwent laparotomy for hepatic artery ligation (see below). The intraoperative findings in the 38 laparotomized patients confirmed the preoperative classification in all cases.

Results

From a total of 54 patients 37 underwent laparotomy for possible tumour resection. Of 19 expansively growing tumours (pushing tumours), 18 were resectable. One expansile hepatocellular tumour involving the right lobe and segment IV of the left lobe of the liver in a 70-year-old patient was, before operation, considered to be technically removable. However, because of his age and poor general health laparotomy for resection was not initially performed. Embolization was attempted but failed because of anatomical vascular problems. The patient was subsequently explored surgically for planned hepatic artery ligation.

Of the seven dependent, hanging tumours six were resected. An hepatocellular carcinoma infiltrating the transverse colon of a 70-year-old patient was not removed surgically; although a resection appeared technically possible, it was doubted whether a combined resection of the liver and colon could be tolerated by the patient. This judgement sadly proved true, as the combined resection was later performed in another hospital after which the patient succumbed.

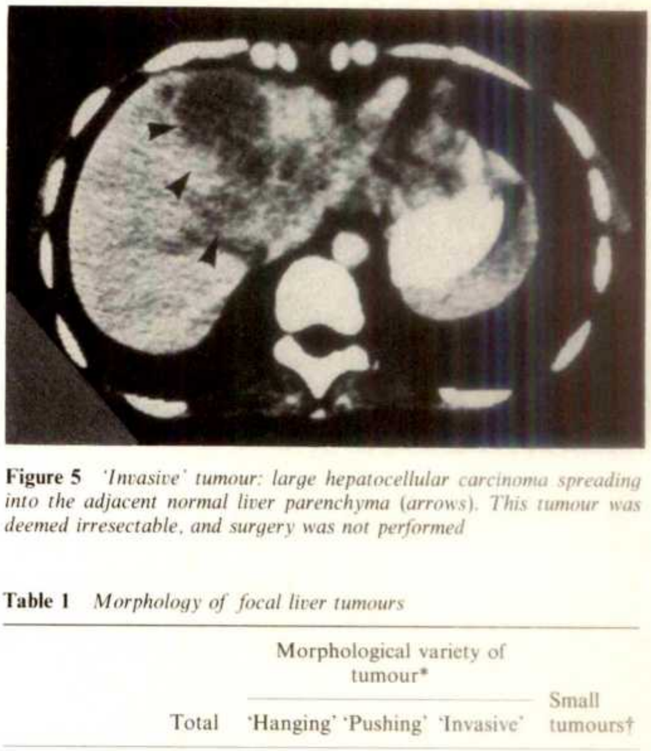

Figure 5 *'Invasive' tumour: large hepatocellular carcinoma spreading into the adjacent normal liver parenchyma (arrows). This tumour was deemed irresectable, and surgery was not performed*

Actual resection	33	6	18	0	9

* The morphological varieties of tumour are described in the 'Materials and methods' section; † small tumours cannot be classified because they do not display gross morphological differences

Only one infiltrating invasive tumour was assessed as resectable before operation: during the operation it proved to be irresectable due to infiltration of vital structures. In the other 16 patients with invasive tumours, laparotomy for resection was not performed as these lesions were not considered resectable by radiological assessment. Two of the patients underwent hepatic artery ligation and one an embolization procedure.

In all, nine of the 11 tumours too small to be classified were removed; the other two were not resected because previously undetected diffuse small liver metastases were found at the time of operation.

The dependent hanging variety of tumour was only encountered with hepatocellular carcinoma. The majority of invasive tumours were also hepatocellular in origin, while most of the pushing expansile tumours were metastatic. It is of interest to note that of 38 patients preoperatively considered to be resectable only five were not. In this series there was one postoperative death, 24 h after laparotomy, in a patient with a metastatic 'APUD' lesion. The overall resectability rate was therefore 61 per cent (33 of 54 cases), and 86 per cent of those lesions preoperatively assessed as resectable by this clinical classification were ultimately successfully resected (33 of 38 cases).

Discussion

There are no clearly defined and uniformly accepted criteria that determine resectability of large benign or malignant liver tumours. Preoperative assessment of resectability is of value but, even with modern imaging techniques such as ultrasonography, computed tomography, angiography, cavography and portography, the ultimate resectability of a given lesion often remains uncertain until operation. This is especially true for large liver lesions where the lack of clear criteria about whether a tumour can be resected or not may lead either to unwarranted laparotomy in unsuitable cases or withholding of an operation because of incorrect preoperative judgement of irresectability. Simple criteria which may allow a clear definition of the possibility of resection were therefore sought. The classification that was developed is based on the gross morphological appearance of liver tumours as displayed by ultrasonography, computed tomography and angiography. It has been found to be reasonably predictive of resectability. Of the 38 patients classified as resectable based on preoperative assessment, 37 underwent laparotomy with the intention of resection and 33 ultimately underwent resection. Two further cases were technically resectable but because of the poor general condition of the patients and/or local invasion of the tumour surgery was not undertaken. Indeed, from a technical point of view, all 19 expansile pushing tumours and all dependent hanging tumours were resectable despite their often considerable size, while all large invasive tumours were not resectable.

Hanging tumours should always be explored and may often be resected without formal anatomical procedures by simply amputating the small rim of liver tissue connecting the dependent mass to the liver. This point is important to recognize. Because only minimal amounts of uninvolved liver tissue is removed, such procedures may be tolerated even in patients with decreased overall liver function due to cirrhosis. Large expansile pushing tumours are resectable surprisingly frequently and the experienced hepatobiliary surgeon should not be deterred from exploration of these patients for resection, despite the often intimidating size of such tumours. Invasive tumours can only be resected in exceptional cases and therefore exploration should rarely be performed.

We would not expect this observed pattern of behaviour of large focal liver tumours to carry any significant biological implication given the heterogeneity of tumour types included for analysis. It must be noted that the distinction between pushing, hanging and invasive tumours may occasionally be difficult to determine in individual cases, although in our experience the preoperative impression generally proved accurate in predicting the findings at laparotomy. The proposed classification may certainly be criticized as being somewhat artificial. None the less, this clinical concept may provide a useful framework with which to approach the problem of resectability.

Alkaline battery-induced tracheo-oesophageal fistula

A. Vaishnav and L. Spitz*

*Royal Hospital, Muscat, Oman and *Hospital for Sick Children, Great Ormond Street, London, UK*

Correspondence to: Mr A. Vaishnav, Royal Hospital, PO Box 2331, Muscat, Oman

The rapid propagation of small electronic gadgets and toys controlled by alkaline batteries has brought these potentially lethal objects within the reach of small children whose natural instinct is to put everything into the mouth. Tracheo-oesophageal fistula caused by alkaline battery ingestion is a rare complication but highlights the hazards of ignoring these foreign bodies.

Case report

A 16-month-old girl was admitted with dysphagia of 4 weeks' duration. Chest radiography showed a coin-shaped foreign body in the upper oesophagus (*Figure 1*), which was removed endoscopically. The object was a 1-cm diameter watch battery which the child had swallowed several weeks earlier.

Postoperatively, the child continued to have feeding problems which failed to resolve with nasogastric feeds. A barium swallow showed a large tracheo-oesophageal fistula at the level of the thoracic inlet (*Figure 2*). Nasogastric feeding was continued, and chest physiotherapy and antibiotics were commenced to improve her nutritional and respiratory status.

Three weeks later, via a right-sided cervical approach, a 1-cm diameter fistula was found between the trachea and the oesophagus. The fistula was divided and the defects repaired with 4–0 silk sutures. A postoperative oesophageal leak closed spontaneously, and a repeat contrast study was satisfactory. Oral feeding was re-established, but 6 weeks later the child was readmitted with a radiologically confirmed recurrent fistula.

Re-exploration revealed a 3-mm diameter tracheo-oesophageal fistula which was divided. The trachea and oesophagus were completely separated over a 5-cm length and the defects were repaired with 4–0 polydiaxonone sutures. A 5-cm square patch of GORE-TEX® (W. L. Gore and Associates Incorporated) was laid in between the trachea and oesophagus and was sutured to the trachea.

A temporary oesophageal leak occurred after operation but a contrast study 6 weeks later failed to detect recurrence of the fistula. The symptoms of coughing with feeds persisted and a repeat study confirmed a second recurrence of the tracheo-oesophageal fistula. The child was then referred to the Hospital for Sick Children, Great Ormond Street, for further management.

The recurrence of the tracheo-oesophageal fistula was confirmed endoscopically. A ureteric catheter was passed into the oesophagus through the fistula at bronchoscopy, via a transverse cervical incision; the trachea and oesophagus were exposed with considerable difficulty because of dense fibrosis and the fistula was identified. The tracheal defect was repaired with interrupted 4–0 Prolene® (Ethicon Ltd., Edinburgh, UK) sutures. A 3-cm length of oesophagus including the fistula was resected and an end-to-end anastomosis was performed in two layers with 4–0 polyglycolic acid sutures. Omohyoid muscle was mobilized and placed between the trachea and oesophagus.

Repeat endoscopy at 3 weeks confirmed successful repair. The child remains symptom-free 9 months after operation.

Discussion

Oesophageal perforations can be caused by batteries, leading to severe mediastinitis and occasionally to exsanguinating haemorrhage. Foreign bodies that pass into the stomach are expected to be excreted without incident. Alkaline batteries, however, need close observation as they have a tendency to open and cause alkaline erosion and even perforation of the stomach.

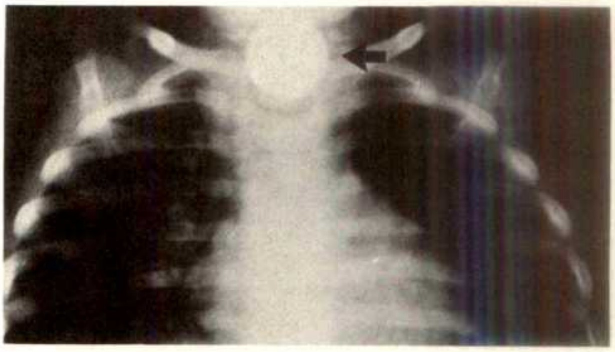

Figure 1 *Plain radiograph of the chest showing the foreign body lodged at the thoracic inlet*

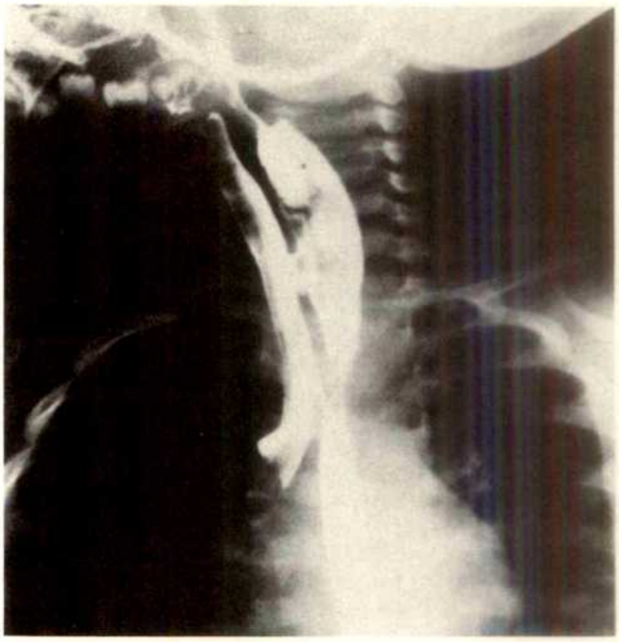

Figure 2 *Contrast swallow showing the large tracheo-oesophageal fistula*

Tracheo-oesophageal fistula caused by a foreign body is rare, and of six cases previously reported only one was due to an alkaline battery[1,2]. An additional case has been reported where a large fistula was found at necropsy in a child who died from severe mediastinitis and haemorrhage following alkaline battery ingestion[3]. Alkaline battery ingestion is a true emergency and, if lodged in the oesophagus, the battery must be promptly removed by endoscopy.

Repair of an acquired corrosive tracheo-oesophageal fistula by simple closure is unsuitable as the adjacent tissue is also affected. Wide excision is recommended if recurrence is to be avoided.

Bile leaks after simple cholecystectomy

Z. Rayter, C. Tonge*, C. E. Bennett†, P. S. Robinson* and M. H. Thomas

*Departments of Surgery, *Nuclear Medicine and †Radiology, St. Peter's Hospital, Chertsey, Surrey KT16 0PZ, UK*

Correspondence to:
Mr M. H. Thomas

Drains after cholecystectomy are used commonly to avoid biliary leaks and subsequent peritonitis. Thirty-five patients who had had cholecystectomy without drainage underwent ^{99m}*Tc-labelled dimethylphenylcarbamoylmethyliminodiacetic acid (HIDA) and ultrasound scans the morning after surgery. Biliary leaks detected by positive HIDA scans occurred in 11 patients. Subhepatic fluid collections were seen on 20 ultrasound scans. There was no relation between biliary leaks and subhepatic collections. Many of the collections were not seen on the HIDA scan, suggesting that they contained blood and not bile. Many of the patients with bile leaks showed no fluid collection. Clinical complications were few and evenly distributed between those with positive and negative scans. We conclude that bile leaks are not an occasional event but occur after 31 per cent of undrained cholecystectomies and that these bile leaks remain clinically unimportant.*

Keywords: Cholecystectomy, bile, peritonitis, drain

The debate about whether drains should be employed after elective cholecystectomy continues and conflicting results have been reported[1–5]. Recent studies and opinion have favoured the omission of drains[4–6]. Nevertheless, the majority of surgeons continue to employ drains even for uncomplicated cholecystectomy[7]. The main reason for this continuing practice is the fear of leakage after operation[8,9]. Drains are placed routinely by many surgeons to catch the occasional leak, although the incidence and significance of bile leakage after cholecystectomy remains unknown. It is known, however, that loculated fluid collections occur in the subhepatic space following simple cholecystectomy[5]. These collections spontaneously resolve and are of little clinical importance. The composition of these collections is not known, although they must contain blood, bile or a mixture of these fluids. The purpose of this study was to investigate the incidence of biliary leaks after elective cholecystectomy in patients not drained after surgery, and to assess the clinical significance of such leaks.

Patients and methods

Informed consent before surgery was obtained in 35 patients undergoing elective cholecystectomy for gallstones: the mean age was 56·4 years (range 27–81 years), and 17 were men. Antibiotic prophylaxis consisted of one dose of cephazolin (1 g) intravenously at induction of anaesthesia. A right upper transverse incision was employed and operative choledochography was performed. A standard antegrade cholecystectomy was undertaken and haemostasis secured with diathermy. No drainage was used and the gallbladder bed was not closed with peritoneum. Patients in whom the operative choledochogram revealed that exploration of the common bile duct was necessary were excluded from the study. The wound was closed with continuous nylon and subcuticular Prolene® (Ethicon Ltd., Edinburgh, UK). Some of the operations were technically difficult and the term simple cholecystectomy was used to denote removal of the gallbladder without other procedures, such as opening the bile duct or duodenum. The length of operation and blood loss were recorded.

At the completion of skin closure 290–330 MBq ^{99m}Tc-labelled dimethylphenylcarbamoylmethyliminodiacetic acid (HIDA) was injected intravenously and the time of the injection was noted.

On the first day after operation a HIDA scan of the whole abdomen was performed using an IGE 400T tomographic γ camera (International General Electric, Slough, UK) linked to a DEC PDP 11/34 computer (Nuclear Diagnostics, North Fleet, UK). The level of radioactivity of ^{99m}Tc-labelled bile in the right upper quadrant and whole abdominal radioactivity were expressed as counts per second (c.p.s.). To allow for the decay of technetium the corrected counts per second were calculated from the formula: c.p.s. $\times\, t_d/t_{\frac{1}{2}} \times 0{\cdot}693^{-e}$, where t_d is the decay time (time elapsed from injection of radionuclide to performance of scan), $t_{\frac{1}{2}}$ is the half-life of ^{99m}Tc, and e is the exponential. Scans were interpreted by an independent specialist in nuclear medicine. The leakage of bile into the gallbladder bed was estimated by the right upper quadrant radioactivity expressed as a percentage of whole abdomen radioactivity.

Immediately after the HIDA scan an ultrasound examination of the right upper quadrant was performed and the diameter of any collection measured in two planes. The volume of the collections was estimated by averaging the diameters to obtain the mean radius (r) and using the formula $V = 4\pi r^3/3$.

In one patient with a collection noted on ultrasound, the subhepatic fluid was aspirated and submitted for radioactive analysis using the γ counter.

The complications recorded after operation included respiratory tract and wound infection, unexplained pyrexia and urinary retention. Respiratory tract infection was defined as the production of purulent sputum with fever, and wound infection as purulent discharge from the wound. Unexplained pyrexia was defined as occurring when the patient had a pyrexia of 38°C or more for 24 h or more with no cause detected.

Results

A positive HIDA scan showed radioactivity in the right upper quadrant which was outside the alimentary tract and indicated a leakage of bile during the early postoperative period (up to 16–24 h after surgery). Eleven patients had positive HIDA scans reported. These had a mean right upper quadrant:whole abdomen radioactivity value of 51 per cent (range 22–77 per cent). Negative HIDA scans were found in 24 patients with a right upper quadrant:whole abdomen radioactivity value of 2 per cent (range 0–17 per cent). No recordable right upper quadrant radioactivity was seen in 17 patients, and seven had a mean right upper quadrant:whole abdomen value of 6·8 per cent. Positive HIDA scans indicating bile leaks were demonstrated in ten of 17 men and one of 18 women (*Table 1*). The length of operation was not significantly different in HIDA-positive patients (55 min) compared with HIDA-negative patients (60 min), and blood loss was negligible in all cases. There was no association with a particular surgeon.

Loculated fluid collections demonstrated by ultrasound were present in 20 patients. The mean volume was 17 ml (range 3–113 ml). Collections were equally distributed between the sexes, and the mean ages of patients with or without collections were similar. Operating time was also the same in those with positive and negative ultrasound scans. There was no relationship between HIDA and ultrasound scan results (*Table 2*). Six of 11 patients with positive HIDA scans had no collection

HIDA, $^{99\mathrm{m}}$Tc-labelled dimethylphenylcarbamoylmethyliminodiacetic acid

detected by ultrasound, and 15 collections were seen in 24 patients whose HIDA scans were negative. Only nine patients had negative HIDA and ultrasound scans.

One HIDA-negative patient with a subhepatic fluid collection detected by ultrasound had this collection aspirated. Serosanguinous fluid was obtained, confirming the ultrasound scan appearances. Analysis of the fluid by a γ counter showed a level of radioactivity similar to background radiation (9·0 *versus* 8·3 c.p.s.), thus confirming the absence of radioactive bile in accordance with the negative HIDA scan.

Postoperative complications occurred with similar frequency in patients with and without a biliary leak or collection (*Table 3*).

Discussion

We have shown that biliary leaks occur in 31 per cent of patients after cholecystectomy, and yet clinically significant bile leakage is uncommon[4,5,10,11]. The method of choice for detecting bile leaks postoperatively is $^{99\mathrm{m}}$Tc-labelled HIDA scanning[12,13]. The gallbladder, common bile duct and early accumulation in the duodenum are visualized within 30 min of intravenous administration. Thereafter, the radioactive label can be seen in the gastrointestinal tract[14]. HIDA is cleared into the bile in 2–3 h and so the kinetics of HIDA excretion suggest that the biliary leaks occur within this time. In this study HIDA was administered at the completion of the operation and it is probable that later administration, such as the next day, would not demonstrate the biliary leaks. The importance of delayed views after injection has been stressed[12,13] and our patients were scanned 16–24 h after surgery. Should there be doubt about the source of right upper quadrant activity, a second scan a few hours later can be performed. Radioactivity within the bowel will move on, but that in a collection remains static. False positive results from the bowel were not a problem in this study and scans were easy to interpret.

The good discrimination in right upper quadrant:whole abdomen radioactivity values between positive (51 per cent) and negative (2 per cent) HIDA scans helps to confirm the accuracy of HIDA scanning in detecting biliary leaks.

Our results indicate that a bile leak after cholecystectomy is not an occasional event but occurs in nearly a third of patients, which is a higher proportion than expected. The apparently higher incidence of bile leaks in men is unexplained. The difficulty of the operation as measured by time and blood loss was similar in HIDA-positive and HIDA-negative patients. The amount of bile leaked could be measured only in terms of right upper quadrant:whole abdomen radioactivity values. This does not give the precise volume of bile that had leaked because of difference in scatter of the γ radiation between patients. Only five of 11 patients with a bile leak had a collection detectable by ultrasound. These collections were small (7–12 ml). It should be noted that 15 of 24 patients without a bile leak had a collection detectable by ultrasound and these collections must be composed of blood or haemoserous fluid. One such collection which was aspirated and analysed for radioactivity supports this suggestion.

The proportion of patients (57 per cent) with a loculated fluid collection after surgery is higher than others have found. In one study no undrained patients had a collection detected by ultrasound after cholecystectomy[11]. We have been able to look for smaller collections using a modern ultrasound scanner with good resolution and have confirmed our findings by needle aspiration.

The lack of correlation between a positive HIDA scan and a positive ultrasound scan was unexpected. Bile is a chemical solution, whereas blood is an organic tissue, and it seems they may be treated differently by the peritoneum.

A strongly positive HIDA scan and a negative ultrasound scan were found in six of 11 HIDA-positive patients. We conclude that pure bile can leak into the peritoneal cavity while blood is localized as a collection in the subhepatic space. Ultrasonography is therefore not a good method of detecting pure bile leakage. We suggest that those five patients in whom both scans were positive had a mixture of bile and blood in the subhepatic space but that it was the blood constituent that caused the collection to form. All our patients were undrained, but previous reports have indicated that drains may influence the composition of leaked fluid and subhepatic collections[5,11].

It is likely that the bile leakage comes from small biliary radicles damaged by dissection of the gallbladder bed. Bile and blood have previously been shown to be readily reabsorbed by the peritoneum[5,8,11]. None of these leaks was clinically significant, and no patient developed a complication specifically related to bile leakage. We suggest that it is the introduction of infection into these harmless bile leaks, as may happen with the placing of a drain, that can render them potentially dangerous.

A total of 519 patients presenting with carcinoma of the caecum in the Plymouth Health District between 1975 and 1987 were reviewed. The clinical course was determined in relation to patients with and without a history of previous appendicectomy. There was no difference in the incidence of previous appendicectomy between patients with carcinoma of the caecum and an age and sex matched control group. The presence of synchronous carcinomas and/or adenomas was unrelated to previous appendicectomy. Ten patients presented with appendicitis and 11 with a mucocele of the appendix as the first sign of carcinoma of the caecum. Previous appendicectomy was associated with a higher incidence of local fixity, invasion of the abdominal wall, metastatic spread and poor differentiation. These differences were reflected in a significantly lower resection rate for carcinomas in patients who had previously undergone appendicectomy. The survival of patients who had previously had appendicectomy was significantly reduced. Four independent prognostic factors for survival were identified using multivariate discriminant analysis. These were Dukes' classification, local invasion, tumour differentiation and previous appendicectomy. Local recurrence was more common in patients who had previously had appendicectomy and was often in the old appendicectomy wound itself. Appendicectomy does not increase the risk of carcinogenesis in the caecum. In this study a history of appendicectomy was an independent risk factor for survival and significantly worsened the prognosis for patients who subsequently developed carcinoma of the caecum.

Keywords: Appendicectomy, carcinoma, caecum.

Colorectal cancer is a major health problem in the western world with over 100 000 new cases and 50 000 deaths attributable to the disease reported each year in the USA[1] There is evidence that the distribution of cancer within the large bowel is changing in the USA, with an increasing proportion of tumours occurring in the right colon and fewer in the rectum[2,3] To date, however, this change has not been noted in the UK where carcinoma of the caecum and ascending colon accounts for from 15 to 25 per cent of all large bowel cancers[4–7]. Carcinoma of the caecum is often locally advanced at presentation and this has been attributed to the relative paucity of symptoms until late in the disease process[4,8–12] Another, and as yet unassessed, reason for these tumours being locally advanced might be previous surgery such as appendicectomy. This study therefore questions the possible association of previous appendicectomy and carcinoma of the caecum in a large, unselected, and consecutive group of patients with these tumours.

Patients and methods

This study includes all 553 patients with carcinoma of the caecum who presented in the Plymouth Health District (population 412 000) from January 1975 to July 1987, inclusive Patients were identified by reference to hospital records, health authority records, discharge summaries, pathology reports, cancer registry office figures, and all coroner's and hospital autopsies The notes of all patients were closely examined by the authors and a record was made of the presentation, past operative history, operative findings, and histology. In 34 patients incomplete information was available leaving 519 cases for analysis Each of the 519 patients studied fully had a definite histological diagnosis of adenocarcinoma For the purpose of this study carcinoma of the caecum was defined as tumours the margins of which were within 10 cm of the ileocaecal valve Tumours of the right colon and hepatic flexure with a proximal margin further than 10 cm from the ileocaecal valve were not studied. Dukes' classification was as defined in the Large Bowel Cancer Project[4,13]. When no lymph nodes were identified in the resected specimen and there was no evidence of distant spread these tumours were classified as Dukes' B. Local malignant invasion was determined by the surgeon in tumours not resected and from histological examination of resected specimens Local recurrence was defined as convincing evidence of recurrence of cancer in the right side of the abdomen or at the anastomosis, but did not include hepatic or peritoneal secondaries[4]. The median follow-up of these 519 patients was 74 months (range from 9 months to 14 years).

Particular reference was made to a past history of appendicectomy, and further information was obtained from pathological examination of right hemicolectomy specimens. The time between appendicectomy and a diagnosis of carcinoma of the caecum was noted, as was whether the appendicectomy was performed for appendicitis or during the course of another operation An age and sex matched group of 519 patients with no known abdominal pathology, undergoing breast, hernia, and varicose vein surgery was also studied to determine the incidence of previous abdominal operations

Clinicopathological details of the 519 patients with carcinoma of the caecum were analysed to determine differences between those with and without a history of appendicectomy The χ^2 test was used for statistical analysis

The effect of various factors on survival was examined in 458 of 519 patients who were followed up for 2 years The factors assessed were age, sex, previous appendicectomy, emergency or elective presentation, Dukes' classification, tumour differentiation, and local invasion Initially a univariate analysis using the χ^2 test was performed for each factor against the number surviving at 2 years. Subsequently, a multivariate discriminant analysis was performed to identify factors of independent prognostic significance for survival at 2 years The analysis was carried out using the Statistical Package for the Social Sciences–X (SPSS-X, SPSS UK Ltd, Walton-on-Thames, UK) Survival curves to 10 years for patients with and without a history of appendicectomy were constructed by the life table method[14] and include both in-hospital mortality and those cancers discovered at autopsy Age adjustment was performed by comparison with figures for England and Wales from 1980 to 1982[15].

Results

During the time period studied, 553 patients were found to have a carcinoma of the caecum or ascending colon and their median age was 73 years (range 14–96 years); 55·9 per cent were older than 70 years and 18·5 per cent were older than 80 years. Of these patients 330 (59·7 per cent) were women and 223 (40·3 per cent) were men. Surgery was performed in 518 patients (93·6 per cent), 25 did not have an operation and in ten cases the diagnosis was made at autopsy. Thirty-four patients were excluded because of inadequate past history or histology, or because of incomplete follow-up

Previous operations

Of the 519 patients in whom information was available, 133 (25·6 per cent) had previously undergone an appendicectomy, 43 (8·3 per cent) a cholecystectomy, 22 (4·2 per cent) a 'gastric' operation and 38 (12·3 per cent of 310 women) a hysterectomy. In 24 of the patients who had undergone cholecystectomy and in 20 who had a previous hysterectomy an appendicectomy was performed at the same time. Thus 89 appendicectomies were performed for suspected appendicitis and 44 as a secondary procedure. No information was available on the degree of appendiceal inflammation.

Of the 519 control patients 120 (23·1 per cent) had undergone a previous appendicectomy, an incidence similar to the study group ($\chi^2=2\cdot29$, $P>0\cdot05$). Cholecystectomy had been performed on 30 control patients (5·8 per cent), 53 had undergone a hysterectomy (17·1 per cent of 310 women) and 18 (3·5 per cent) a 'gastric' operation.

Clinicopathological details

The clinical details of patients with and without a history of appendicectomy are shown in *Table 1*. There was no difference in the sex ratio, age, or mode of presentation between the two groups of patients. Patients with a history of appendicectomy had a significantly poorer Dukes' classification (*Table 2*) and also had less well differentiated carcinomas (*Table 3*). There was no relationship between the distance of the caecal carcinoma from the ileocaecal valve (1–10 cm) and the clinicopathological details relating to a history of appendicectomy.

Twenty patients (5·2 per cent) with no history of appendicectomy had synchronous large bowel carcinomas and 74 (19·2 per cent) had adenomas. The corresponding figures for patients who had had appendicectomy were similar, with ten carcinomas (7·5 per cent) and 30 (22·6 per cent) adenomas. Thirteen metachronous carcinomas and ten adenomas have to date been found in patients with no history of appendicectomy. Similarly, two metachronous carcinomas and two adenomas have been found in patients who had previously undergone appendicectomy.

Table 1 *Clinical details in patients with and without a history of appendicectomy*

	No appendicectomy ($n=386$)	Appendicectomy ($n=133$)
Men	160 (41·5)	49 (36·8)
Women	226 (58·5)	84 (63·2)

Percentage aged > 70 years	54·2	60·9
Emergency	131 (33·9)	47 (35·3)
Elective	249 (64·5)	84 (63·2)
Autopsy	6 (1·6)	2 (1·5)

Values in parentheses are percentages

Table 2 *Dukes' classification in patients with and without a history of appendicectomy*

Dukes' classification	No appendicectomy ($n=386$)	Appendicectomy ($n=133$)
A	21 (5·4)	5 (3·8)
B	176 (45·6)	33 (24·8)
C	133 (34·5)	57 (42·9)
'D'	56 (14·5)	38 (28·6)

$\chi^2=23\cdot88$, $P<0\cdot001$ (overall appendicectomy *versus* no appendicectomy); values in parentheses are percentages

Table 3 *Tumour differentiation in patients with and without a history of appendicectomy*

Differentiation	No appendicectomy ($n=386$)	Appendicectomy ($n=133$)
Well	80 (20·7)	12 (9·0)
Moderate	210 (54·4)	72 (54·1)
Poor	96 (24·9)	49 (36·8)

$\chi^2=12\cdot72$, $P<0\cdot01$ (overall appendicectomy *versus* no appendicectomy); values in parentheses are percentages

Table 4 *Histology: the relationship of abdominal wall fixity to Dukes' classification*

	Number of fixed tumours		
Dukes' classification	No appendicectomy ($n=386$)	Appendicectomy ($n=133$)	*P* value
A	0/21	0/5	
B	4/176 (2·3)*	12/33 (36)	<0·001
C	8/133 (6·0)	20/57 (35)	<0·001
'D'	10/56 (18)*	21/38 (55)	<0·001

Significance values are for no appendicectomy *versus* appendicectomy. * $P<0\cdot001$ (Dukes' B *versus* 'D'); values in parentheses are percentages

Local invasion into the abdominal wall and muscle was present in 22 (5·7 per cent) of the patients without previous appendicectomy and 13 (59 per cent) of these tumours were resected. In contrast 53 (39·8 per cent) patients who had previously undergone appendicectomy had evidence of local invasion ($\chi^2=93\cdot3$, $P<0\cdot001$) and 36 (68 per cent) were resected. Thus 71 per cent of tumours with local invasion were associated with a history of appendicectomy. It was not possible to determine whether the local invasion was inflammatory or malignant in the 26 unresected cases. The relationship of local invasion to Dukes' classification is shown in *Table 4*. The incidence of local invasion was higher for all Dukes' classifications (except A) in patients who had previously undergone appendicectomy. In patients with no history of appendicectomy the incidence of local invasion increased with Dukes' classification whereas in patients who had previously undergone appendicectomy this relationship was less marked. The number of cases of local invasion into abdominal viscera was similar in the two groups of patients at 29 of 386 (7·5 per cent) and six of 133 (4·5 per cent), respectively.

Histopathology of the appendix

Ten patients with carcinoma of the caecum presented with acute appendicitis and 11 had a mucocele of the appendix. These 21 patients were allotted to the 'no previous appendicectomy' group. Three patients had an appendicectomy within 1 year of the diagnosis of carcinoma of the caecum. The incidence of acute appendicitis as the presenting symptom of carcinoma of the caecum was thus 13 of 386 (3·4 per cent) of patients at risk. In three patients a discharging fistula through an old appendicectomy scar was the first sign of carcinoma of the caecum.

Surgery

Of the patients with no history of appendicectomy, 360 of 386 (93·3 per cent) underwent resection and 26 (6·7 per cent) had either no operation (14, 3·6 per cent) or a palliative procedure

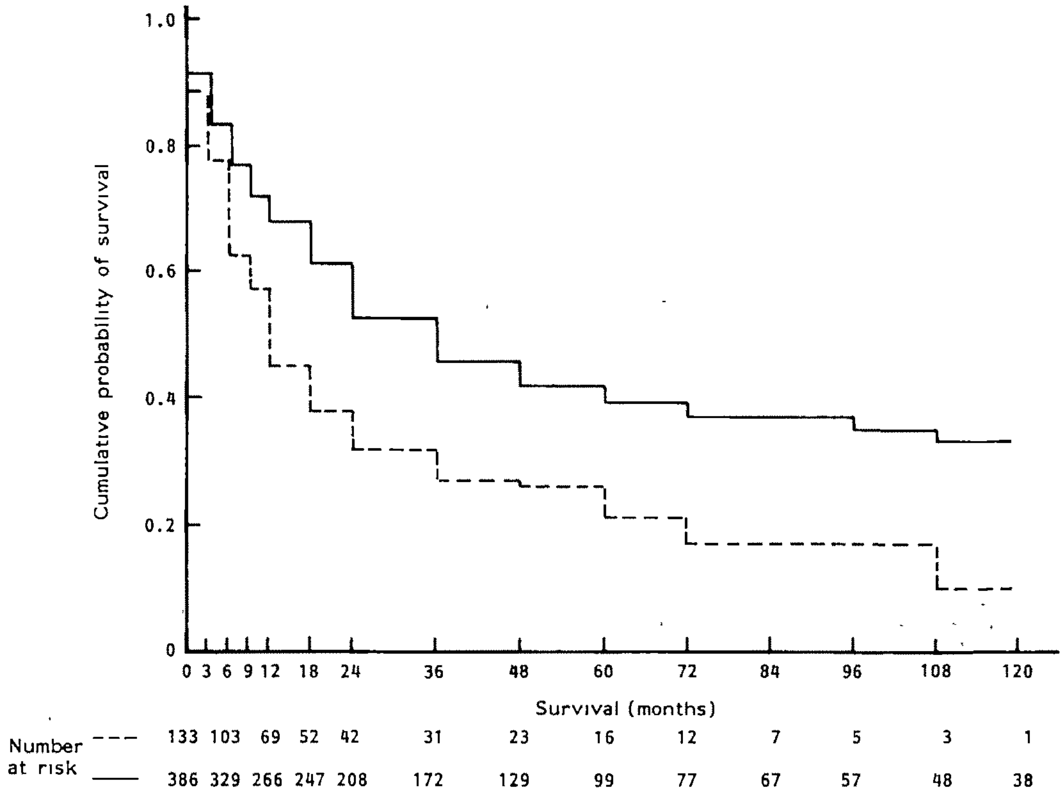

Figure 1 *Survival of patients with and without a history of appendicectomy; ——, no appendicectomy, ---, appendicectomy The number of patients at risk are given*

(12, 3·1 per cent) In contrast only 100 of 133 (75·2 per cent) patients with a history of appendicectomy underwent resection ($\chi^2=32\cdot1$, $P<0\cdot001$) with 33 (24·8 per cent) patients having either no operation (six, 4·5 per cent) or a palliative procedure (27, 20·3 per cent). Overall 59 patients had no resection performed, 32 underwent palliative bypass, eight had laparotomy only, 12 had no operation, and eight tumours were discovered at autopsy; most of these were Dukes' 'D' tumours.

Survival

The overall survival rate of the 519 patients is shown in *Figure 1*, and was significantly less for patients with a history of appendicectomy ($\chi^2=7\cdot75$, $P<0\cdot01$). The 2-year survival rate, based on the 458 patients with 2-year follow-up, for patients with no appendicectomy was 53·7 per cent (182 of 339), and for patients with previous appendicectomy it was 26·1 per cent (31 of 119) ($P<0\cdot001$).

Univariate statistical analysis identified five factors that were significantly related to survival at 2 years. All factors, their incidence, and the relationship to survival are shown in *Table 5*. On performing a discriminant analysis to allow for the inter-relationship of factors, a model involving just four variables resulted In deriving this model a step-wise approach was adopted, with a significance criterion of $P<0\cdot05$ for the inclusion of variables in the model. The variables contained in the final model, in the order of inclusion, were Dukes' classification (P for inclusion $<0\cdot001$), local invasion ($P<0\cdot001$), tumour differentiation ($P<0\cdot001$), and a past history of appendicectomy ($P=0\cdot027$). The above model correctly predicted the outcome (i.e. survival at 2 years) for 79 per cent of cases when it was applied to the whole data set from which the model was derived.

Local recurrence was more commonly observed in patients with a previous appendicectomy and occurred in 18 of 56 (32·1 per cent) and 24 of 183 (13·1 per cent) cases, respectively ($\chi^2=10\cdot72$, $P<0\cdot01$). Local recurrence in an old appendix wound occurred in ten cases. Anastomotic recurrence was seen in 12 cases, 2·6 per cent of right hemicolectomies, and was unrelated to a history of appendicectomy.

Table 5 *Factors related to survival in the univariate analysis*

	Percentage of patients	Percentage of patients alive at 2 years	χ^2 test (P value)

Discussion

Colorectal cancer is the second most common malignancy in both men and women in this country with over 38 000 cases and 17 000 deaths being attributable to the disease each year in England and Wales[16]. Carcinomas of the right colon are more common among women, as in this study, in contrast to the rectum where more cases are seen in men[4,5]. A large proportion of patients with right colon cancers are elderly[4,8–10] and we have confirmed this observation, over half our patients being above 70 years of age and nearly one-fifth being older than 80 years.

Although some studies have shown that right-sided colonic cancers are associated with increased[17,18] or decreased[7,19,20] survival compared with other sites in the large bowel, two recent large studies[4,21] found no significant difference in survival for growths throughout the colon and rectum In the Large Bowel Cancer Project[4], however, it was found that tumours of the right colon were more likely to be poorly differentiated and locally advanced in terms of fixation and penetration of the large bowel. In that study a quarter of right colonic cancers were poorly differentiated, 41 per cent were locally fixed, and one-fifth showed evidence of distant metastases. The present study shows similar results with only 5 per cent of tumours being Dukes' A and 14·5 per cent showing evidence of local invasion. Previous authors[8–12,22,23] with smaller numbers of patients, have also commented on the high incidence of local fixity of cancers of the caecum and ascending colon but none has yet investigated the possible relationship between this fixity and previous surgery.

A history of appendicectomy is common and this operation had been performed in over a fifth of our control group of patients. Previous studies have documented appendicectomy rates of 17·5 per cent for men and 33·3 per cent for women in New York[24], and 19·0 per cent for men and 13·0 per cent for women in the UK[25]. These and other studies[26,27] found no relationship between appendicectomy and the later development of colonic cancer and we have confirmed this in the present study. It is of interest that equal numbers of synchronous and metachronous carcinomas and adenomas were seen in patients with and without a history of appendicectomy.

Carcinoma of the caecum rarely presents as acute appendicitis[9–11,28] and we found this mode of presentation in 3·4 per cent of susceptible cases. The possibility of carcinoma of the right colon must be considered in all patients with appendicitis over the age of 50 years, as three of our patients had an appendicectomy within 1 year before carcinoma of the caecum was diagnosed. Three patients also presented with a discharging fistula through an old appendix scar and this confirms the observation of El-Domeiri and Whiteley[12] who found fistulation only when the integrity of the abdominal wall and parietes had been compromised by previous surgery.

In this study a history of appendicectomy was associated with a significantly increased chance of local fixity and invasion of the abdominal wall, and it is noteworthy that over 70 per cent of cancers invading the abdominal wall were associated with previous appendicectomy. Most tumours invading the abdominal wall were resected *en bloc*, and the survival of such patients was then related to the histological stage and grade of the tumour. This confirms previous observations that locally invasive carcinomas of the colon can be resected with good long term results[12,29] The presence of local fixity and invasion of the abdominal wall may relate to adhesions after appendicectomy with scar tissue in the caecal wall, and to the inflammatory changes of appendicitis itself. Unfortunately as many appendicectomies were performed decades earlier we are unable to comment further on this.

It is of interest that patients with a past history of appendicectomy had more advanced and less well differentiated tumours, although it must be emphasised that in a retrospective study there is considerable observer variation among pathologists in relation to histological grading[30]. These factors plus the increased incidence of local fixity led to a significant reduction in resection rates after appendicectomy, although in both groups of patients most of the tumours were resected. The reason for tumours being more advanced after previous appendicectomy may relate to delayed presentation with difficulty in examination due to scar tissue. There was, however, no difference in the number of patients presenting as an emergency nor in the symptoms at presentation between the two groups of patients. Local adhesion formation may be conducive to greater local tumour spread, raising the possibility that an intact serosal surface may provide some barrier to local tumour spread Previous surgery in the form of appendicectomy might also be associated with adaptive hyperplasia[31,32] of the epithelium in the caecum and this could possibly lead to altered growth characteristics in the carcinoma itself. In addition, it is interesting to speculate that the loss of lymphoid tissue in the appendix could alter the immune response to local carcinomas in the caecum.

The survival of patients with carcinoma of the caecum who had previously undergone appendicectomy was significantly lower than those patients with no such operative history. Univariate analysis identified five highly significant factors relating to survival at 2 years. Multivariate analysis demonstrated that four of these factors were of independent prognostic significance for survival. The most important were the well recognized factors of Dukes' classification, tumour differentiation, and local invasion[33,34]. However, this study also identified that previous appendicectomy contributed significantly as an independent risk factor for survival. It is also noteworthy that age in itself was not a significant risk factor, confirming recent reports[35].

There was also a significant increase in the incidence of local recurrence after previous appendicectomy and this was often in the appendix scar itself. This might relate to the presence of more aggressive carcinomas or to incomplete tumour clearance at operation because of scar tissue and adhesions. A case may be made for removal of the old appendix scar with the carcinoma in patients undergoing curative surgery and this observation might therefore lead surgeons to resect areas of bowel adhesion widely when they are in the vicinity of a primary tumour. Anastomotic recurrence was low in this study at 2·6 per cent and this confirms the earlier study of Wright *et al.*[36] who reported tumour recurrence in 0·7 per cent of ileocolic anastomoses compared with 12 per cent of colocolic anastomoses. As recently emphasised by Umpleby and Williamson[32], however, this low incidence of ileocolic recurrence may relate to the relative difficulty in diagnosing an ileocolic anastomotic tumour before it presents as a massive local recurrence.

The present study has demonstrated for the first time that previous appendicectomy has an independent influence on outcome and significantly decreases survival in patients who subsequently develop a carcinoma of the caecum. The reason for this is unclear but may relate to delayed presentation, altered growth characteristics, or postoperative adhesions with scar tissue. A prospective study is needed to evaluate more fully the possible detrimental effect of previous appendicectomy on both cancer of the caecum and cancer throughout the large bowel.

Birmingham B15 2PH

One hundred and twenty-four patients had a postanal repair for the treatment of faecal incontinence between January 1976 and July 1987. One hundred and sixteen of these patients have been followed up for more than 1 year with a median follow-up of 5 years. Incontinence was improved in 81 per cent of patients. Furthermore, bowel frequency fell: 58 per cent had more than four bowel movements before operation compared with 19 per cent after operation. However, 60 per cent of patients still claimed urgency, 76 per cent still leaked faeces and 52 per cent continued to wear pads after the operation. Maximum resting anal pressure and maximum squeeze pressure did not change significantly after operation either in patients whose bowel control was improved or in those who were not. The results indicate that the quality of continence after postanal repair is poor.

Keywords: Maximum resting anal pressure, maximum squeeze pressure, bowel frequency

Faecal incontinence is physically and emotionally disabling. Although all age groups may be affected, it is rare before the third decade, but increases thereafter. The majority of patients with faecal incontinence have evidence of nerve damage to the pelvic floor and/or external sphincter[1]. Many of these patients also have a history of obstetric trauma:prolonged labour, forceps delivery or third degree tears[2]. Other patients develop incontinence secondary to chronic straining, rectal prolapse, iatrogenic damage, particularly after anal dilatation or fistula operation, and some have neurological disorders or congenital anomalies[3]. Incontinence may also occur secondary to faecal impaction or after sphincter-saving operations[4].

The aim of postanal repair is to restore the anorectal angle[5] and the flap valve of the puborectalis[6]. Early functional results of postanal repair reported from St. Mark's Hospital, London, UK, and this unit have been encouraging[7], but in these studies follow-up has been short and many surgeons express the view that long-term results are disappointing. We have a large series of patients operated on by one surgeon over 11 years where long-term follow-up is now available. Results have been assessed objectively by an independent observer using a specific questionnaire and physiological monitoring.

Patients and methods

Between January 1976 and July 1987, 124 patients with faecal incontinence underwent a postanal repair Incontinent patients were selected for operation if they had low resting and squeeze pressures, no rectal prolapse, a normal sphincter ring with a normal perineal body, and electromyographic evidence of pelvic floor neuropathy with poor recruitment during attempted pelvic floor contraction together with an obtuse anorectal angle during videoproctography.

Symptoms and clinical findings were recorded on specific follow-up data sheets. Preoperative and postoperative anal canal pressures were studied in 68 patients. All patients were reviewed to assess the functional results and quality of continence at 12 months after operation and annually thereafter.

Anal canal pressures were measured in the left lateral position after rectal examination using a closed water-filled balloon probe attached to a transducer and pen recorder Measurements of resting and squeeze pressures were performed at 1-cm intervals 1–5 cm from the anal verge. Maximum basal and squeeze pressures were taken as the highest resting pressure in the anal canal and the highest pressures recorded after voluntary contraction respectively.

Operative procedure

Postanal repair was performed using the intersphincteric approach described by Parks[8]. However, a number of adaptations were made which have already been described[7] These departures from Parks' original operation include avoidance of a weak adrenaline solution, use of a transverse incision, raising a thicker anterior skin flap and mass closure of the pelvic floor with interrupted Dexon® (Davis and Geck, Gosport, UK). The ileococcygeus, ischiococcygeus and pubococcygeus were co-opted in the midline posteriorly after removing the anterior retractor. If there was any rectal damage, contamination or anterior skin flap ischaemia, the wound was left open and the necrotic skin was excised.

Although there were a wide variety of disorders and pathophysiological abnormalities associated with incontinence, all of the patients in this survey were offered postanal repair because there was clinical, electromyographic or videoprotographic evidence of a weak pelvic floor and a deficient puborectalis sling. Although patients with a history of obstetric trauma and previous operations on the anal canal were offered repair they all had physiological or radiographic evidence of a pelvic floor abnormality and an obtuse anorectal angle.

Results

The median age of the 124 patients was 59 years (range 20–84 years). Thirteen patients (10 per cent) were men and 111 (90 per cent) were women.

The aetiology and associated disorders are shown in *Table 1*. Twenty patients had had a full-thickness rectal prolapse; although a previous rectopexy had successfully controlled the prolapse these patients remained incontinent. Idiopathic faecal incontinence was found in 61 patients, only two of whom were men. Of the 59 women, 30 gave a history of prolonged labour or forceps delivery. Twenty-one women had sustained severe obstetric trauma with electromyographic and proctographic evidence of a pelvic floor neuropathy. Thirteen patients had had previous anal surgery and four had had other operations (*Table 1*) but all had evidence of pelvic floor damage.

Thirty-nine patients (31 per cent) had undergone previous treatment for faecal incontinence (*Table 2*).

Of 124 patients having postanal repair, 18 patients (15 per cent) developed a complication (*Table 3*). One obese diabetic patient died 7 days after the operation from a massive pulmonary embolus. Seven patients developed wound sepsis and ten further patients developed ischaemic necrosis in the anterior skin flap. A fistula from the rectum to the incision

0007-1323/89/101054–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

occurred in three patients as a result of iatrogenic damage; these patients have all been successfully managed by repair after raising a proximal colostomy. In three other cases iatrogenic damage was not accompanied by a fistula. Three patients developed a large wound haematoma and one further patient was returned to theatre because of bleeding.

Functional results and quality of continence has been assessed in 116 patients who have been followed-up for between 1 and 10 years. The results were not assessed in eight patients because five patients had had their operation within 3 months of this review, one patient died and two have been lost to follow-up. Ninety-four patients (81 per cent) stated that the degree of continence was definitely improved after the operation, 12 (10 per cent) patients said that improvement had only been minor and 10 said they were no better or worse and all 10 have now had a colostomy (*Table 4*). In the 94 patients who achieved a definite improvement in continence, 61 per cent did so within 3 months of the operation; it took a further 3–6 months in 18 per cent, 6–12 months in 15 per cent, and in 6 per cent of the patients continence was only achieved after 1 year.

Bowel frequency was compared before and after operation (*Figure 1*). Sixty-seven patients (58 per cent) opened their bowels more than four times a day before the operation, compared with only 22 patients (19 per cent) after operation. Although bowel frequency was reduced after operation, eight patients opened their bowels more than six times a day even after the operation and all had persistent and troublesome incontinence

Quality of continence was assessed by asking patients about urgency, leakage of faeces, soiling of pads and ability to discriminate between flatus and faeces (*Figure 2*). Eighty-nine per cent of the patients claimed urgency before operation and 60 per cent still had urgency after operation. Ninety-three per cent experienced involuntary leakage of faeces at least once a month preoperatively and this persisted after operation in 76 per cent Eighty-four per cent of patients soiled pads before operation, and 52 per cent continued to wear pads because of soiling after operation. Forty-five patients (39 per cent) had been unable to discriminate between flatus and faeces before operation, compared with 29 patients (25 per cent) after operation. When results were analysed according to the aetiology of incontinence, patients who had had a previous rectopexy had significantly worse results than all other groups. Only 44 per cent were improved by postanal repair after a previous rectopexy compared with 89 per cent of those with idiopathic incontinence ($P<0.05$). All patients needed to wear a pad

because of soiling when postanal repair was used for persistent incontinence after rectopexy compared with 38 per cent of those with idiopathic incontinence ($P<0{\cdot}01$) and 30 per cent of those who had sustained third-degree tears ($P<0{\cdot}05$). There was no apparent difference in the incidence of improved results, urgency, leakage or the use of pads when the group with idiopathic faecal incontinence was compared with those who had sustained obstetric trauma.

Anal canal pressures were measured before operation in almost all subjects but postoperative manometry was only repeated in 68 patients; of these, 50 patients stated that incontinence was improved after the operation and 18 that it was not (*Table 5*). Maximum anal and maximum squeeze pressures did not change significantly after the operation overall or in either subgroup.

Discussion

In order to assess the functional results of postanal repair we analysed several aspects of continence such as bowel frequency, urgency, leakage of faeces, soiling of pads and ability to discriminate between gas and stool. The results were disappointing. 60 per cent of the patients continued to complain of urgency, 76 per cent experienced involuntary faecal leakage and 52 per cent of the patients found that they continued to soil pads after the operation. Despite this, 81 per cent of the patients claimed that bowel control was improved. These paradoxical results might be explained by the fact that the patients seemed to feel that bowel control was better even if the degree of urgency or faecal leakage was only slightly improved. These results indicate that although postanal repair is usually able to improve the degree of faecal incontinence, the quality of continence is poor. Critical evaluation by an unbiased observer probably explains why results from this report appear to be inferior to those previously published from this unit. These results do not suggest that continence deteriorates with time; indeed, in some patients, continence was only restored a year after postanal repair.

Functional results did not correlate with maximum resting pressure or maximum squeeze pressures. Parks believed that the factor most reliably associated with good results was the ability to restore the anorectal angle[9]. Hence, the operation would not have been expected to cause a rise in anal pressure. Indeed, early repeated measurement of anal canal pressures in this unit showed no significant change after postanal repair[10], though later studies suggested that postanal repair resulted in a significant rise in maximum resting pressures[7]. Browning *et al.*[11] observed a significant increase both in maximum resting and squeeze pressures. The most likely explanation for these changes is that the repair also plicates the posterior fibres of the external sphincter.

Thirty-nine patients (31 per cent) had had previous treatment for incontinence. Twenty patients had persistent incontinence despite an earlier rectopexy for rectal prolapse In ten of the 20 patients in this group, results of postanal repair were disappointing and only eight claimed any functional improvement following the operation. Results were significantly worse than in patients with idiopathic faecal incontinence. As a result of these observations, postanal repair for persistent incontinence after rectopexy is rarely advised; furthermore, a combined postanal repair and abdominal rectopexy is not recommended as it is difficult to predict those patients who will remain incontinent. There is also an increased risk of perineal infection if the operations are performed synchronously. Thirteen patients previously had treatment using an electrical device but functional improvement was minimal[12].

This study can be criticized for including 21 patients with obstetric injury, but all had electromyographic evidence of a pelvic floor neuropathy and an obtuse anorectal angle on videoproctography Furthermore, results in these patients did not differ from those with idiopathic faecal incontinence. We believe that in many patients with a history of obstetric trauma, incontinence is more commonly due to a weak pelvic floor rather than a defect in the sphincter ring. Indeed, disruption of the sphincter ring is treated by sphincter repair[7]; despite this practice, unpublished long-term results from this unit suggest that persistent incontinence may occur after this procedure because of an underlying pelvic floor abnormality.

The main factors associated with failure of postanal repair are severe muscle degeneration, the irritable colon syndrome and sepsis at the operation site[13,14]. Severe muscle degeneration may be identified preoperatively by measurement of mean fibre density and a hyperactive sigmoid colon can be identified using preoperative sigmoid manometry. Results in this series were poor if diarrhoea persisted after operation. Unfortunately, the diarrhoea associated with persistent faecal incontinence is usually unpredictable and episodic and therefore is not amenable to treatment with agents such as loperamide or codeine. Patients should also be told to stop straining postoperatively because in some patients progressive pelvic floor neuropathy is encouraged. A stimulant suppository may help some of these patients. Pelvic floor exercises, anal hygiene and attention to bowel habit should also be encouraged in patients who have an imperfect result. Many individuals find that these measures help to achieve a degree of continence that is certainly preferable to a stoma. Sepsis should now no longer be a risk factor, particularly if contaminated wounds are left open; using this policy only seven patients developed wound sepsis after the operation (6 per cent). Conversely, damage to the rectum resulting in an iatrogenic fistula is generally attended by poor results. If the rectum is inadvertently injured at the time of repair, the defect should be sutured as an intra-anal procedure using a Parks' retractor; this policy has been successful in three recent injuries and a covering stoma was not necessary.

Although the quality of continence reported in this critical assessment of postanal repair is far from perfect, almost without exception the patients are grateful for the improvement that has been achieved. Furthermore, they consider their quality of life is infinitely better than having to face the prospect of a permanent stoma.

Anterior sphincter plication and levatorplasty in the treatment of faecal incontinence

R. Miller, W. J. Orrom, H. Cornes, G. Duthie and D. C. C. Bartolo

Department of Surgery, Bristol Royal Infirmary, Bristol, UK

Correspondence to:
Mr R Miller, Royal United Hospital, Bath, UK

The surgical treatment of faecal incontinence has been traditionally divided into sphincteroplasty for sphincter disruption and postanal repair for idiopathic cases. However, many studies have failed to show a correlation between outcome and change in the anorectal angle. This study was carried out to determine the effectiveness of anterior sphincteroplasty and levatorplasty in the treatment of faecal incontinence, regardless of aetiology. Thirty consecutive patients underwent surgery, 14 with traumatic sphincter injuries and 16 with idiopathic faecal incontinence. A satisfactory clinical result was obtained in ten (71 per cent) patients in the traumatic group and in ten (62 per cent) in the idiopathic group. This was associated with a significant increase in maximum voluntary contraction pressure in the traumatic group and in those patients who had a good result in the idiopathic group (traumatic: preoperative median 80 cmH$_2$O (range 50–115 cmH$_2$O) versus *postoperative 115 cmH$_2$O (75–290 cmH$_2$O),* $P<0{\cdot}005$; *idiopathic: preoperative 105 cmH$_2$O (45–190 cmH$_2$O)* versus *postoperative 120 cmH$_2$O (45–230 cmH$_2$O),* $P<0{\cdot}05$; *Wilcoxon paired signed ranks test). There was also a significant improvement in anal sensation in the upper anal canal in both groups (traumatic: preoperative mean 17 mA* versus *postoperative 11 mA,* $P<0{\cdot}05$; *idiopathic: preoperative 24 mA* versus *postoperative 9 mA,* $P<0{\cdot}02$). *The anorectal angle increased in the idiopathic group at rest (preoperative median 105° (range 86–152°)* versus *postoperative 118° (95–180°),* $P<0{\cdot}05$). *In conclusion, the type of approach (anterior or posterior) and the anorectal angle are irrelevant to the outcome of surgery for idiopathic faecal incontinence. Success appears to be related more to improved sphincter pressure and anal sensation.*

Keywords: Anterior sphincter repair, incontinence, levatorplasty

It has been suggested that the acute anorectal angle produced by the action of the puborectalis muscle is fundamental to the maintenance of continence by creating a flap-valve effect[1,2]. Many investigators have described an obtuse anorectal angle in patients with idiopathic faecal incontinence[1,3–5]. The operation of postanal repair was devised to recreate the acute angle and thereby improve continence[2].

However, some patients with idiopathic faecal incontinence do not have an obtuse anorectal angle[6,7] and the pressure changes during a Valsalva manoeuvre suggest that continence is maintained by sphincteric action rather than a flap-valve effect[8]. Furthermore it has been demonstrated by proctographic techniques that the anterior rectal wall is not in contact with the upper anal canal during periods of high intra-abdominal pressure[9,10].

These findings have led us to modify our approach to the management of incontinence. In the past we have subdivided patients on the basis of clinical, physiological and electromyographic findings into two main groups: those with traumatic sphincter disruption (usually secondary to obstetric injury) and those with idiopathic faecal incontinence. The former were offered anterior sphincter plication[11] and the latter postanal repair[12].

From 1987 onwards we have used an anterior approach to treat all patients with incontinence, irrespective of the aetiology. In this paper we describe the outcome of patients treated by such an approach. A detailed clinical and physiological assessment was made before and after surgery in an attempt to determine those factors responsible for improved continence.

Patients and methods

From January 1987 to November 1988, 38 patients have had anterior sphincter surgery at the Bristol Royal Infirmary. Thirty patients have had complete preoperative and postoperative investigations and are reported here. Fourteen patients had an anterior sphincter tear demonstrated by electromyography (EMG) or at operation, and in 16 no sphincter injury could be demonstrated and these patients were therefore classified as having idiopathic faecal incontinence. Clinical details are given in *Table 1*

Clinical assessment

All patients had a thorough clinical examination including examination of the lumbosacral plexus, digital rectal examination, sigmoidoscopy and proctoscopy. The degree of incontinence was assessed and graded as described by Browning and Parks[13]: Grade A, continent to solids and liquids and also to flatus; Grade B, continent to solid and usually liquid but incontinent to flatus; Grade C, partial return of function with generally acceptable continence for solid stool but no control over liquid or flatus; and Grade D, continued faecal leakage. Patients with

Table 1 *Clinical details of patients*

	Anterior sphincter tear ($n=14$)	Idiopathic faecal incontinence ($n=16$)
Age (years)	32 (23–49)	66 (36–80)
Parity	2 (0–3)	2 (0–7)
Follow-up duration (months)	5 (1–18)	4 (2–12)

Values are median (range)

Grade A or B were defined as having a successful result, and those with Grades C and D as failures.

Operative technique

Surgery, after preparation with Picolax® (Nordic Pharmaceuticals Ltd., Feltham, UK), was performed by one surgeon (D.C.C.B.). Prophylactic antibiotics were also used: three perioperative doses of cefuroxime (750 mg) and metronidazole (500 mg). The technique of sphincter plication for patients with an obstetric sphincter injury was based on that described by Parks and McPartlin[11]. In addition, however, the levator space was entered and these muscles were plicated between the rectum and vagina using two superficial and two deep 2/0 Prolene® (Ethicon Ltd., Edinburgh, UK) sutures. This was performed in an attempt to lengthen the anal canal and augment the perineal body. Through an anterior incision the cut and retracted ends of the sphincter were separated from the internal sphincter, which was plicated with 2/0 Vicryl® (Ethicon Ltd.). The ends of the external sphincter were then overlapped and sutured with interrupted 2/0 Prolene.

In patients with idiopathic faecal incontinence the sphincters were exposed anteriorly using the intersphincteric plane to gain access to the levator muscles. The levators were plicated with interrupted 2/0 Prolene. The external sphincter was then divided in the midline anteriorly and plicated in the same way as for traumatic disruption. The internal sphincter was plicated as described above.

Primary closure after this repair results in excessive tension. The wounds were therefore only partially closed with the small remaining defect left to heal by secondary intention. This invariably occurred within 4–6 weeks. Covering stomas were not used.

Manometry

The manometric system consisted of a water-filled balloon, 6 mm in diameter, connected via non-distensible tubing to a Statham transducer (P23Gb, Spectromed, Coventry, UK). Using a station pull-through technique the sphincter length, maximum resting pressure and maximum voluntary contraction pressure were measured. This technique has been described in detail previously[14]

Anal sensation

Anal mucosal electrosensitivity was measured in the lower, middle and upper thirds of the anal canal as defined by manometry. A catheter carrying two platinum electrodes 1 cm apart was inserted into the anal canal and a small electric current from a constant current generator (Department of Medical Physics, Bristol Royal Infirmary, Bristol, UK) was passed across the electrodes[15]. The threshold to this stimulus was determined three times and the mean value recorded.

Electromyography

In eight of the 14 patients with a history of obstetric trauma a gap in the sphincter was demonstrated preoperatively using a Medelec EMG recorder (Type MES, Medelec, Woking, UK) and a conventional concentric needle (Type 13L49, Dantec, Copenhagen, Denmark). In the remaining six patients the sphincter defect was found at operation.

Proctography

The patient was placed in the left lateral position and 50 ml of a semisolid mixture of barium sulphate and potato starch was injected into the rectum. The anal canal was outlined by a string of metal beads connected to a wooden ball placed in the rectum. The anorectal angle was defined as the angle between the central axis of the rectum and the anal canal as shown by the beads. The degree of perineal descent was measured from the highest bead in the anal canal and the plane of the perineum. This represents the line connecting the anterior portion of the symphysis pubis with the lowermost part of the coccyx. Lateral radiographs were taken in the positions of rest, maximum sphincter contraction (squeeze) and/or bearing down as if at stool (strain).

Table 2 *The number of patients undergoing surgery and the outcome in the traumatic and idiopathic groups*

	Traumatic		Idiopathic	
Grade	Preoperative	Postoperative	Preoperative	Postoperative
A	0	7	0	5
B	0	3	0	5
C	7	3	6	3
D	7	1	10	3

Grade A, continent to solids, liquids and flatus; Grade B, continent to solid and liquid, incontinent to flatus; Grade C, continent to solids, Grade D, continued faecal leakage

Statistical analysis

The Mann–Whitney *U* test was used to compare individual groups. The Wilcoxon paired signed ranks test was used to compare preoperative and postoperative results in the same patients. Results are quoted as medians with ranges in parentheses, unless otherwise stated.

Results

Clinical

Ten of the 14 patients in the traumatic group (71 per cent) had a successful result, their continence being either Grade A or B after operation. In those patients who had idiopathic faecal incontinence, ten of 16 were successful (62 per cent; *Table 2*).

Manometry

There was no significant change in sphincter length or maximum resting pressure following surgery in either group. Surgery improved the maximum voluntary contraction pressure in the traumatic group (preoperative median 80 cmH_2O (range 50–115 cmH_2O) *versus* postoperative 115 cmH_2O (75–290 cmH_2O), $P<0{\cdot}005$) but had no significant effect on maximum voluntary contraction in the idiopathic group as a whole (preoperative 107 cmH_2O (5–200 cmH_2O) *versus* postoperative 117 cmH_2O(45–230 cmH_2O), n.s.; *Table 3*). However the subgroup of ten idiopathic patients who had a successful result maximum voluntary contraction did improve significantly (preoperative 105 cmH_2O (45–190 cmH_2O) *versus* postoperative 120 cmH_2O (45–230 cmH_2O), $P<0{\cdot}05$). This was not true for resting pressures. However, it is interesting that taking all the patients together, those who had a good result clinically had a significantly higher preoperative resting pressure than those who were failures (60 cmH_2O (10–105 cmH_2O) *versus* 40 cmH_2O(0–74 cmH_2O, $P<0{\cdot}05$, Mann–Whitney *U* test).

Mucosal electrosensitivity

In the lower and midzones of the anal canal there was no change in sensitivity following surgery (*Table 3*). In the upper zone however there was a marked improvement in sensation in both the traumatic group (preoperative mean 17 mA *versus* postoperative 11 mA, $P<0{\cdot}05$) and the idiopathic group (preoperative 24 mA *versus* postoperative 9 mA, $P<0{\cdot}02$)

Radiology

There was an increase in anorectal angle at rest in the idiopathic group (preoperative median 105° (range 86–152°) *versus* postoperative 118° (95–180°), $P<0{\cdot}05$). The only other changes were in the traumatic group where the angle was more acute on squeeze and straining after operation (*Table 3*).

There was no change in the degree of perineal descent in either group.

Discussion

The operation of postanal repair stemmed from the flap-valve theory of continence but the evidence against this concept is now overwhelming. Firstly, a significant number of patients with idiopathic faecal incontinence do not have an obtuse anorectal angle[6,7]. Secondly, if the theory were correct one would expect a high pressure zone just above the anal canal during a Valsalva manoeuvre and Read[8] has demonstrated that this is not the case. He suggested that the high pressure zone in the anal canal was of primary importance. Furthermore, proctographic studies have failed to demonstrate the mechanism[9]; indeed the reverse is the case. Using videoproctography with additional sphincter EMG and anorectal pressure monitoring Bartolo *et al.* demonstrated that the anterior rectal wall does not occlude the anal canal during rises in intra-abdominal pressure[10]; continence under these circumstances was maintained principally by sphincteric action.

The findings of the current study support the view that the sphincters act by creating a high pressure zone in the anal canal.

Table 3 *The results of surgery in the traumatic and idiopathic groups as defined by the changes in physiological and radiological parameters*

	Traumatic		Idiopathic	
	Preoperative	Postoperative	Preoperative	Postoperative

Surgery was designed to improve the function of the external sphincter and this was achieved in the traumatic group and in those patients with idiopathic incontinence who had a successful result. We were not able however to demonstrate an increase in the length of the functioning sphincter, a factor which has been associated with successful postanal repair[6].

Keighley and Fielding[16] have also described an improvement in voluntary contraction pressures following sphincter repair for traumatic disruption. There is, however, a considerable divergence of opinion regarding the effect of postanal repair on anal sphincter pressures. Browning and Parks[13] described an increase in voluntary pressures but others have shown a rise in resting pressure alone[16] or no change in either component[6].

In this series, surgery for incontinence resulted in improved sensation in the upper zone of the anal canal. We have previously described a similar improvement in upper anal canal sensation following postanal repair[7] but others have found no change[17]. Any reduction in sensory thresholds is probably due to lax or prolapsed anal mucosa being drawn back up into the anal canal by the plication of the levators and external sphincter.

Awareness of the presence and nature of rectal contents is an important factor in maintaining normal continence and therefore this improved sensation may well contribute to the success of surgery.

The clinical outcome for traumatic sphincter injury in this study is similar to that reported by others[18–20]. With an anterior approach in the idiopathic group we have achieved a satisfactory outcome in 62 per cent despite the anorectal angle becoming more obtuse at rest. This degree of success is nearly identical to that of postanal repair on our unit (59 per cent) as well as that reported by others[7,16,21].

In the traumatic group the anorectal angle did become more acute both on squeezing and straining but not at rest. However, these are not the patients in whom an obtuse angle is cited as a cause of incontinence. They had a clearly defined breach in the external sphincter and the changes in anorectal angle probably reflect the improved action of the levators following their plication. Also, it is difficult to see how such a small change in angle (9°) could affect continence.

In conclusion, it appears that the type of approach (anterior or posterior) and the anorectal angle are irrelevant to the outcome of surgery for idiopathic faecal incontinence. Success is more related to improved sphincter pressures and anal sensation The anterior approach has the advantage that preoperative EMG to demonstrate a sphincter defect is not necessary.

Professor W. O Kirwan

In 126 consecutive patients operated on for carcinoma of the lower two-thirds of the rectum, a consistent policy of sphincter preservation resulted in 100 (79 per cent) having anterior resection and 22 (17 per cent) abdominoperineal resection. Perioperative complications in the anterior resection group were: death (two patients), clinical leakage (three patients), pulmonary embolism (five patients), pelvic haematoma (one patient), small bowel obstruction (one patient) and wound sepsis (six patients). Of 55 patients who had a potentially curative anterior resection with follow-up of at least 2 years, one developed local recurrence. Five per cent of patients had significant continence problems. Low anterior resection for carcinoma is associated with low perioperative morbidity, satisfactory functional results and acceptable local recurrence rates.

Keywords: Rectal carcinoma, anterior resection morbidity, neorectal function, local recurrence

In the surgery of rectal cancer the emphasis has moved from abdominoperineal excision to anterior resection. The change, however, outside specialized units[1,2] has been slow, reluctant and sometimes controversial[3]. To justify the increased frequency of anterior resection it must be shown that: the difficult problems of anastomotic dehiscence and pelvic sepsis[4,5] can be overcome, closer longitudinal margins of resection[6,7] do not result in an increased incidence of local recurrence[3,8], and acceptable continence is achieved[9]. In this paper we report the outcome of a vigorous anterior resection policy in 126 consecutive patients with cancer of the lower and midrectum, in terms of morbidity, mortality rate, cancer clearance and continence

Patients and methods

In 126 patients operated on for cancer of the mid or lower rectum, 100 (79 per cent) had anterior resection, 22 (17 per cent) abdominoperineal resection, three (2 per cent) Hartmann's resection and in one the tumour was not resected.

The mean ages of patients for anterior resection and abdominoperineal resection were 65 and 60 years respectively Sixty-two per cent of anterior resections and 72 per cent of abdominoperineal resections were performed in male patients. Tumour height is given in *Table 1* Mean tumour height in abdominoperineal resection was 3 cm and in anterior resection 8 cm Dukes' classification is given in *Table 2*. Surgery was considered palliative in 24 patients (24 per cent) having anterior resections (13 Dukes' 'D'. 11 extensive local spread) and in ten (46 per cent) patients having abdominoperineal resections

Anterior resection methodology

Standard methodology was used. Under anaesthesia, the rectum was irrigated with saline until clear and 50 ml povidone-iodine was instilled A full length midline incision was made. The entire left colon, including the splenic flexure, was mobilized and the left colic artery was ligated The sigmoid colon and complete mesorectum were excised and the descending colon was used for the neorectum

Anastomosis was fashioned with the EEA® (US Surgical Corporation and Auto Suture UK, Ascot, UK) instrument and tested for leakage of air Suction irrigation of the presacral space was performed for 4 days to prevent haematoma. The minimal distal clearance margin was 1 cm. Temporary transverse colostomy was performed in 38 per cent of patients overall but only in 16 per cent of the last 50 patients. A water-soluble contrast enema was performed on 92 patients on the tenth postoperative day.

For the initial 70 cases in the entire series, bladder management was by urethral catheter but for the latter 56 patients fine bore suprapubic catheterization was used Prophylactic subcutaneous low dose heparin was not used during this series, but has now become our practice.

Table 1 *Height of tumour above anal margin in patients* (n = *100*) *who had low anterior resection*

Height (cm)	No of patients
3–5	21
6–7	25
8–9	21
10–12	33

Dukes' classification	Anterior resection (*n* = 100)	Abdominoperineal resection (*n* = 22)
A	22	—
B	42	9 (41)
C	23	10 (46)
'D'	13	3 (14)

Values in parentheses are percentages

Deaths occurring within 2 months of surgery have been classified as operative mortality Patients were followed up prospectively to monitor recurrence and bowel function The term 'potentially curative resection' was used where removal of the primary tumour was histologically complete longitudinally and laterally with no evidence of distant metastases[10]

Results

Perioperative morbidity accruing from rectal resection is shown in *Table 3*

Three anterior resection patients developed clinical anastomotic leakage. None had a protective proximal stoma In one, the pelvic irrigation system malfunctioned allowing a haematoma to develop. Seven patients developed subclinical radiological anastomotic leakage. In the last 50 patients, clinical leakage was 2 per cent and radiological leakage 6 per cent. No patient died directly as a result of anastomotic leakage One patient, however, became debilitated by such leakage and died of pulmonary embolism. No patient developed anastomotic stricture requiring surgical intervention. Pelvic haematoma resulted in small bowel obstruction in one anterior resection patient.

In 57 anterior resection patients, catheterized urethrally, there was proven urinary tract infection in 19 per cent, in the latter part of the series the incidence was 11 per cent in 43

patients catheterized suprapubically. In the entire series two of 126 patients required transurethral prostatectomy for retention.

Bowel function was assessed by interviewing 80 surviving patients 1 year after operation about their bowel function, both at the time of interview and before surgery[11]. Results are shown in *Table 4*. Eighty-one per cent of patients had normal continence. All four patients who had major continence problems (grades 4 and 5) were women and had tumours below 7 cm.

Fifty-five patients underwent anterior resection which the surgeon considered potentially curative, and had a mean follow-up of 42 months (range 24–84 months). Four died of unrelated causes and seven from distant metastases with no evidence of pelvic recurrence. One patient who had a Dukes' C tumour died of local pelvic wall recurrence. A further patient was found 2 years after operation to have a metachronous rectal tumour separate from the suture line, which was treated by a potentially curative Hartmann's resection The incidence of local recurrence in patients with potentially curative tumours was 2 per cent. One of the 12 patients who had a potentially curative abdominoperineal resection developed local recurrence. Of 11 patients having anterior resection who were considered to have extensive local spread at surgery, seven developed pelvic recurrence, two systemic recurrence and two died of unrelated disease within 2 years.

Discussion

Twenty-two per cent of patients who had anterior resection were Dukes' A, while in the abdominoperineal group no patient had Dukes' A disease. Dukes' B and 'D' were roughly of equal incidence for both procedures but there was a 2:1 preponderance of Dukes' C disease in the abdominoperineal group. The disease treated by anterior resection was less severe than that requiring abdominoperineal resection. The earlier the disease is diagnosed the more likely is the patient to retain his sphincters because early tumours, even very low in the rectum, are safely managed by anterior resection. Advanced tumours very low in the rectum require abdominoperineal resection which, alas, is palliative only in about half of our cases.

Much of the morbidity of anterior resection has historically been due to anastomotic dehiscence[1,4] with rates of from 3 to 18 per cent[5,12]. Diminished performance of temporary colostomy[13] (16 per cent colostomy in the last 50 cases) has not resulted in an increased morbidity rate.

For safe colorectal anastomosis, removal of pelvic haematoma is mandatory[14]. Furthermore, the use of sigmoid colon for anastomosis is highly undesirable because it is often narrow, has muscle hypertrophy, may have diverticular disease, and its use, without full left colon mobilization, may result in the presence of intolerable tension at the anastomosis. We undertake full left colonic and splenic flexure mobilization in every case. This, in addition, mobilizes the attachment of the left part of the greater omentum and facilitates its placement in the pelvis. In the early part of the series we unwisely anastomosed cases of extensive pelvic disease. We no longer do this because of subsequent morbidity requiring diversion. Many quoted cases of 'local recurrence' are, in fact, examples of residual tumour, the result of extensive extrarectal ramification, and this is widely recognized as a bad prognostic indicator[15]. True local recurrence is found at or very near the anastomosis, and in its initial stages is superficial and mobile. True local recurrence was seen once in the present series of anterior resections (2 per cent) and even this patient had Dukes' C disease and the recurrence was initially in the side wall of the pelvis. It is considered to be a local recurrence because the operating surgeon decided at the time of resection that the tumour was curable.

This level of recurrence (2 per cent) has been sustained in spite of resections performed extremely close to the tumour and we have shown elsewhere that even with a margin of resection of 1 cm on the gross specimen, involvement of the excised doughnut by tumour is extremely rare[7].

Unquestionably, imperfections of continence sometimes occur and persist following low anterior resection. In this series, 4 per cent of patients had incontinence requiring colostomy, and all were women. It is likely that they were suffering from traction neuropathy of their pelvic nerves[16] and preoperative manometric evaluation has enabled us to predict some patients who may be predisposed to such incontinence[17]. The presence of a poor sphincter pressure profile in a patient who otherwise might have an anterior resection is not an indication for abdominoperineal excision, as a Hartmann's procedure would suffice and spare the patient the morbidity of a perineal wound.

None of our patients had a colonic pouch[18]. After a period of adaptation of up to 12 months after operation, rectal compliance improves in the majority of patients at which time satisfactory continence is achieved[19]. In the present series 81 per cent of patients considered they had normal continence and the majority of the remainder considered their condition acceptable.

Seven per cent of patients with anterior resection developed radiologically confirmed deep vein thrombosis. Five patients developed pulmonary embolism and two died. We had been reluctant to institute a policy of prophylactic subcutaneous low dose heparin in patients requiring such extensive pelvic dissection but all patients are now given prophylactic heparin. Of the patients who developed deep vein thrombosis, all but one were male, and the more difficult problems of the male pelvis may account for this[20].

We conclude that many of the technical difficulties of low anterior resection have been overcome and that acceptable morbidity and mortality rates can be achieved[21]. Improved understanding of the surgical pathology of rectal cancer makes narrow margins of distant clearance acceptable and safe, and the anticipated high level of local recurrence has not emerged. The incidence of serious continence problems following anterior resection is low.

Non-condylomatous perianal disease in homosexual men

This retrospective study details the findings and outcome in 34 homosexual men, out of a total of 177 patients, who underwent surgery for non-condylomatous perianal disease over a 2-year period. Of 34 homosexuals 20 presented with anorectal sepsis compared with 11 of 79 heterosexual male patients ($\chi^2 = 24{\cdot}07$, $P < 0{\cdot}001$). Lesions included chronic intersphincteric abscess (eight patients), anal fistula (seven patients) and chronic intersphincteric abscess and fistula (five patients). Anal fissure occurred in 15 patients, anal ulcer in three, skin tags in six, haemorrhoids in two and Kaposi's sarcoma in one. Eight patients were human immunodeficiency virus (HIV) antibody negative, four were asymptomatic HIV antibody positive, 12 had symptomatic HIV infection using the Centers for Disease Control classification and in ten patients HIV status was unknown. Irrespective of the type of surgery performed, healing occurred within 6 weeks of operation in all HIV antibody negative patients, all asymptomatic HIV antibody positive and in only one of nine patients with symptomatic HIV infection. Eight of nine patients with symptomatic HIV infection failed to heal by this time ($\chi^2 = 8{\cdot}98$, $P < 0{\cdot}05$). These findings suggest that the prevalence of anorectal sepsis in homosexual men is high and that symptomatic HIV infection is an important determinant of progress after surgery.

In recent years there has been an increase in the prevalence of gastrointestinal tract diseases in homosexual men[1,2]. The incidence of human immunodeficiency virus (HIV) infection is also rising[3] and it has been estimated that up to 30 per cent of homosexual men with the acquired immunodeficiency syndrome (AIDS) will develop colorectal or perianal diseases and that more than half of these will require surgery[4]. It seems likely, therefore, that colorectal surgeons will become more frequently involved in the diagnosis and management of anorectal problems in homosexual patients.

The relationship between homosexual activity and gut infections due to a wide variety of sexually transmitted, enteric and opportunistic organisms is becoming widely recognized[1,2,5]. Proctitis and proctocolitis are the most usual clinical manifestations, though perianal ulceration can occur. Similarly, condylomata acuminata are prevalent in homosexual men and the association between human papillomavirus infection and these lesions is established[6].

By contrast, other forms of anorectal disease in homosexual men, such as abscess, fistula and fissure, have received less attention and there is a paucity of information concerning the natural history of these types of perianal disease The purpose of the present study was to review the types of lesion and response to surgical treatment in a group of homosexual men with non-condylomatous perianal disease who were referred to a colorectal surgeon (W.W S.) for further management

Patients and methods

The case records of all homosexual patients who underwent surgery for non-condylomatous perianal disease on the colorectal surgery unit at the Middlesex Hospital during the period from November 1986 to December 1988 were reviewed These patients had originally been referred by general practitioners or genitourinary physicians to the outpatient rectal clinic or were inpatient referals from the AIDS ward at the Middlesex Hospital Particular attention was directed towards the duration of symptoms before operation, sexual practices, previous perianal disease, the presence or absence of sexually transmitted disease, HIV antibody status, the type of perianal lesion and the outcome of surgical treatment.

During the same time period, 143 heterosexual patients also underwent operations for perianal disease. There were 79 male patients (median age 45·5 years, range 15–83 years) and 64 women (median age 47 5 years, range 24–80 years) In these patients, the indications for surgery included haemorrhoids in 55 cases, anal fissure in 30, anal skin tags in 28, perianal abscess or fistula in 19, anterior mucosal prolapse in five, squamous carcinoma in three, hydradenitis suppurativa in two and anal stenosis in one patient. The sexual proclivity of the male heterosexual patients had been established by direct questioning during clerking by the house surgeons

For the purposes of the present study HIV status was classified as. HIV antibody negative; HIV antibody positive–asymptomatic, which included patients who were HIV antibody positive but with no stigmata of AIDS as defined by the Centers for Disease Control (CDC)[7]; HIV antibody positive–symptomatic (with past or present stigmata of AIDS and equivalent to CDC groups III and IV), and HIV antibody status unknown

Results

Thirty-four male homosexual patients out of a total of 177 patients who underwent surgery for non-condylomatous perianal disease during the 2-year period were included in the study. The median age of the homosexual patients at presentation with perianal disease was 33·0 years (range 22–54 years) with a median duration of symptoms before surgery of 2·0 months (range 0·25–84 months). All patients gave a history of participation in penoreceptive anal intercourse. Eleven of the 34 patients had previously suffered from condylomata acuminata and ten patients had previous non-condylomatous lesions which had been treated elsewhere.

Associated sexually transmitted disease

Seventeen patients (50 per cent) had evidence of previous sexually transmitted infection which was not present at the time of presentation with their perianal disease. The types of previous sexually transmitted disease included infection with syphilis (11 cases), hepatitis B virus (11 cases), herpes simplex virus (seven cases), gonorrhoea (six cases), cytomegalovirus (two cases) and *Entamoeba histolytica* (one case). At the time of presentation with perianal lesions, three of the 34 patients exhibited active sexually transmitted disease which included cytomegalovirus

infection in one patient and Herpes simplex infection in two.

HIV status

Eight of the 34 patients were HIV antibody negative and four were HIV antibody positive–asymptomatic (CDC Group II). Twelve patients had symptomatic HIV infection corresponding to CDC Group III in two cases, CDC Group IVa in two, CDC Group IVb in one, CDC Group IVc1 in three, CDC Group IVc2 in three and CDC Group IVd in one patient. Ten patients were not tested for HIV.

Prevalence and types of perianal disease

Forty-seven lesions were encountered in the 34 patients. Anorectal sepsis was present in 20 patients, anal fissure in 15, anal ulcer in three, skin tags in six, haemorrhoids in two and Kaposi's sarcoma in one patient.

Anorectal sepsis. Thirteen of the 20 patients with sepsis had chronic intersphincteric abscesses and in five of these an associated intersphincteric fistula was present. The other seven patients with sepsis presented with anal fistula only. Of these, five were superficial, one was intersphincteric and one was trans-sphincteric. In five of the 20 patients with anorectal sepsis other lesions were present which included anal fissure in three cases and anal ulcer in two. The prevalence of perianal sepsis in the homosexual patients (20 of 34) was significantly greater ($\chi^2 = 24{\cdot}07$, $P < 0{\cdot}001$) than that observed in the heterosexual male patients of whom 11 of 79 underwent surgery for perianal sepsis.

Anal fissures. Only nine of 15 anal fissures were sited solely posteriorly in the anal canal. In the other six patients, the fissure was situated anteriorly in five and both anteriorly and posteriorly in one. Swabs for herpes simplex virus were taken from all fissures and the virus was cultured from two of the 15 patients Six fissures were associated with skin tags, three with anorectal sepsis and two with haemorrhoids The incidence of anal fissures in homosexual men (15 of 34) was not statistically significantly different from that observed in heterosexual male patients (21 of 79; $\chi^2 = 3{\cdot}367$, $P > 0{\cdot}05$).

Anal ulcers. These were situated posteriorly in the anal canal, were oval or circular in shape and between 1 and 2 cm in diameter. They were indolent, with undermined edges, and the base was formed by the internal anal sphincter. One of the three anal ulcers occurred as an isolated lesion, but the other two ulcers were associated with chronic intersphincteric abscesses Two patients had serological evidence of previous cytomegalovirus infection and the cytopathic effects of cytomegalovirus were apparent in biopsy material from one of the ulcers.

Surgical treatment

Nineteen of 20 abscesses or fistulae were laid open. Fissures were treated by either excision and sphincterotomy or anal dilatation (*Table 1*). Examination under anaesthesia and biopsy was the only procedure performed in one patient with chronic intersphincteric abscess because the nature of the lesion was uncertain. The patient with Kaposi's sarcoma underwent examination under anaesthesia only.

Follow-up

Three patients (two HIV antibody positive–symptomatic and one HIV status unknown) defaulted from any follow-up Two other patients were excluded from further analysis. One of these had Kaposi's sarcoma and no operative procedure was undertaken while the remaining patient whose HIV status was unknown underwent biopsy of an intersphincteric abscess which was not considered definitive therapy. Follow-up data for a minimum of 6 weeks after surgery were available for the remaining patients (eight HIV antibody negative, four HIV antibody positive–asymptomatic, nine HIV antibody positive–symptomatic and eight HIV unknown)

Outcome with special reference to HIV status

The proportion of patients with anorectal sepsis and anal fissures was similar in each of the four HIV status subgroups (*Figure 1*). Two of three anal ulcers occurred in HIV antibody positive–symptomatic patients. In the other patient with anal ulcer HIV status was unknown.

Healing of perianal wounds occurred with 6 weeks of surgery in all HIV antibody negative and all HIV antibody positive–asymptomatic patients, but in only one of nine HIV antibody positive–symptomatic patients. Eight out of the nine HIV antibody positive–symptomatic patients had failed to heal by this time and continued to experience symptoms from their perianal lesion This difference in the proportion of patients in each HIV subgroup who exhibited wound healing at 6 weeks was statistically significant ($\chi^2 = 8{\cdot}98$, $P < 0{\cdot}05$). In the eight patients whose HIV status was unknown, six exhibited wound healing at 6 weeks after surgery and two had not healed by this time.

Of those with delayed healing, four of the HIV antibody positive–symptomatic patients failed to exhibit healing at 2, 2,

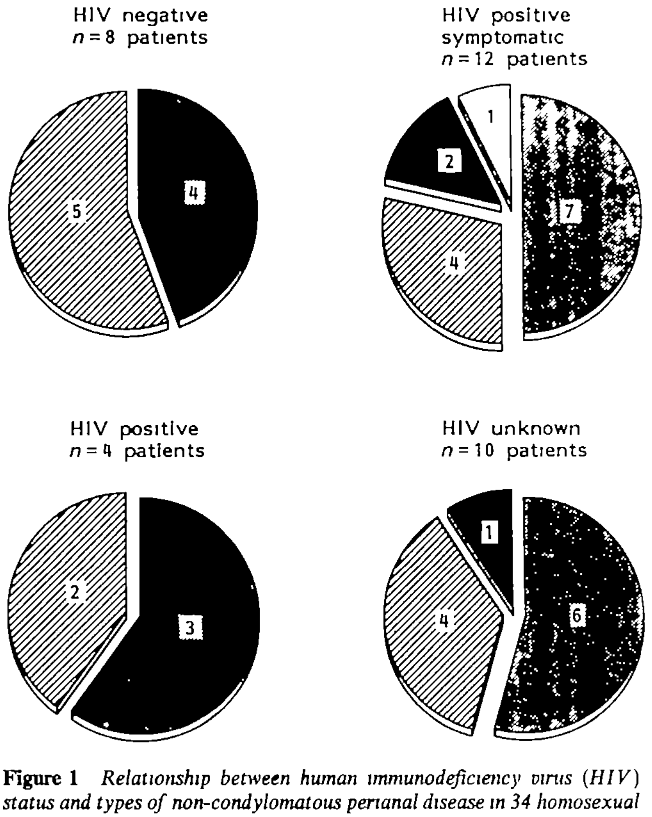

Figure 1 *Relationship between human immunodeficiency virus (HIV) status and types of non-condylomatous perianal disease in 34 homosexual men (values within the pie-chart refer to the number of lesions and not the number of patients which is shown beneath the HIV status),* ▩, *sepsis,* ▨, *fissure,* ■, *ulcer,* □, *Kaposi's sarcoma*

2·5 and 3 months after surgery and were then lost to follow-up. In another four patients with symptomatic HIV infection, healing occurred at 4, 9, 10 and 14 months respectively. Three of these were evaluated by further examination under anaesthesia, but no additional definitive procedure was undertaken. In the two patients with unknown HIV status and delayed healing, one healed successfully at 11 months and the other has not healed 10 months after operation.

Discussion

It is well known that perianal disease in homosexual men may be caused by specific infections[1,2]. Herpes simplex virus can produce multiple perianal ulcers, and painful chancres may accompany primary syphilitic infection[8]. The anorectal region is also a primary target for the opportunistic infections of AIDS, and several authors have noted that organisms not traditionally associated with sexual transmission, such as cytomegalovirus and *Cryptococcus neoformans*, may, in the presence of HIV infection, cause painful anal ulceration[5,9,10,11]. Clearly, all male homosexual patients, particularly those with symptomatic HIV infection, who present with perianal disease should be carefully screened for the presence of an infective agent. Nevertheless, the findings from the present study, in which fewer than 10 per cent of patients had active sexually transmitted disease, illustrate that perianal disease in homosexual men is not always due to sexually transmitted or opportunistic infection.

The spectrum of non-condylomatous perianal disease in the homosexual population has been previously examined by Sim[12]. He reviewed 251 anorectal procedures carried out on 'no-risk' heterosexual and 'at-risk' homosexual patients and demonstrated that both groups displayed similar types of perianal disease. Excluding patients with condylomata acuminata, 65 of 187 'no-risk' and 17 of 45 'at-risk' patients presented with either anal sepsis or fistula[12]. By contrast, in the present series almost two-thirds of homosexual men presented with anorectal sepsis and this proportion was statistically highly significantly greater than that observed in heterosexual male patients who underwent operation over the same period of time. Wexner *et al.*[4], in their study of anorectal disease in male homosexual patients with symptomatic HIV infection, noted that abscess or fistula was the main indication for surgery in 30 of 51 patients. These findings are similar to those of the present study and lend support to the view that the prevalence of anorectal sepsis in homosexual men is high.

The severe and progressive forms of anorectal sepsis that have been reported in patients with AIDS[4,12] were not encountered in the present series. Nevertheless, our findings are in keeping with those of Sim[12] and others[13] who have also noted that chronic abscesses and intersphincteric sepsis are particularly common in homosexual men. The reasons for this are uncertain but, as suggested by Baker and Peppercorn[2], repeated trauma due to receptive anal intercourse and other homosexual practices is likely to be an important aetiological factor. A similar mechanism may also explain the occurrence of atypically situated anal fissures and chronic anal ulcers in these patients.

It has been stated that healing usually proceeds uneventfully in the presence of AIDS[12]. In contrast to this, Wexner *et al.*[4] found that 88 per cent of perianal wounds had not healed 30 days after operation. Our data support those of Wexner *et al.* and indicate that a high proportion of patients with symptomatic HIV infection exhibit delayed healing of perianal wounds and experience considerable morbidity for weeks or months after surgery. These observations are of great concern and carry important therapeutic implications in that, unless the subgroup of homosexual men with symptomatic HIV infection is identified preoperatively by careful clinical examination, serological testing or the assessment of risk factors[14], they may be subjected to operative procedures which exacerbate rather than improve their perianal disease. In the current climate, where HIV testing can only be performed after full consent, it may be that all male homosexual patients should be regarded as potentially symptomatic HIV positive and managed as conservatively as possible.

Thirty-seven patients with previously untreated perianal condylomata acuminata were randomly treated by application of 25 per cent podophyllin or scissor excision. The result of treatment was assessed by an independent observer. At 6 weeks, scissor excision completely cleared the warts from 16 of 18 patients (89 per cent) compared with 15 of 19 patients (79 per cent) treated with podophyllin. Following complete clearance by surgery, two patients had recurrent warts at 18 weeks and a further single patient at 42 weeks, giving a cumulative recurrence rate of 19 per cent. In contrast, five of 15 patients whose warts were cleared by podophyllin had recurrent warts at 18 weeks and a further four at 42 weeks representing a cumulative recurrence rate of 60 per cent ($\chi^2=3{\cdot}95$, *d.f.* $=1$, $P=0{\cdot}05$)*. At 42 weeks six patients (32 per cent) were free of disease in the podophyllin group compared with 13 (72 per cent) in the scissor excision group* ($\chi^2=4{\cdot}6$, *d.f.* $=1$, $P=0{\cdot}03$)*. Scissor excision is therefore preferable to podophyllin application in the treatment of perianal condylomata acuminata.*

Keywords: Condylomata acuminata, podophyllin, scissor excision

Condylomata acuminata (venereal warts) are due to infection with human papillomavirus[1] and present a major public health problem which is increasing in prevalence[2,3]. Treatment of these lesions is generally acknowledged to be difficult, time consuming and to give poor results. The aim of this prospective randomized, controlled study was to compare podophyllin application and scissor excision in the treatment of perianal condylomata acuminata.

Patients and methods

Thirty-seven patients with previously untreated condylomata acuminata entered the trial Patients with genital and/or anal canal involvement above the dentate line, those suffering from other perianal diseases and those receiving topical perianal medication were not included in the study Other exclusion criteria included pregnancy and patients receiving antiviral, immunosuppressive therapy or immune stimulation therapy within 2 months. All sexual partners were examined and treated if necessary. Patients were strongly advised to refrain from sexual intercourse during the treatment period and told to use a condom for 4 months after completion of treatment

The patients were randomly assigned according to the last digit of the number of their hospital notes to treatment with scissor excision or local application of 25 per cent podophyllin in benzoin tincture. The investigator was not aware of the patients' hospital number at time of randomization Scissor excision was carried out according to the method described by Thomson and Grace[4] If the lesions were numerous they were removed in two stages at a 3-week interval. Podophyllin application was as described by Simmons[5] and the treatment was repeated weekly for up to 5 weeks if necessary

Follow-up was carried out by an independent observer, who had no knowledge of the treatment given, at 6, 18 and 42 weeks after the start of treatment. The presence of condylomata acuminata at 6 weeks' follow-up was considered as failure of treatment. The Mann–Whitney U test and χ^2 test with Yates' correction were used for comparison between groups. Confidence intervals were calculated according to Gardiner and Altman[6].

Results

In all, 19 patients were treated with podophyllin and 18 with scissor excision. The two groups were comparable (*Table 1*).

Table 1 *Comparability of groups*

	Podophyllin group ($n=19$)	Surgical group ($n=18$)
Median (range)		
Age (years)	33 (20–51)	30 (21–49)
No. of lesions	14 (6–34)	15 (5–36)
Duration of symptoms (weeks)	12 (7–26)	11 (8–24)
Male:female	12:7	13:5
Number of homosexuals	7	6
Number of females practising anal intercourse	2	1
Number of patients with anal canal lesions below dentate line	3	5

All patients completed the 42 weeks of follow-up. At 6 weeks, scissor excision had completely cleared the warts from 16 of 18 patients compared with 15 of 19 patients treated with podophyllin, giving a failure rate of 11 and 21 per cent respectively. After complete clearance by surgery, two patients had recurrent warts at 18 weeks and a further single patient at 42 weeks, giving a cumulative recurrence rate of 19 per cent In contrast, five of 15 patients whose warts were cleared by podophyllin had recurrent warts at 18 weeks and a further four at 42 weeks, representing a cumulative recurrence rate of 60 per cent. The cumulative recurrence in the podophyllin group was significantly higher than in the scissor excision group ($\chi^2=3{\cdot}95$, d.f. $=1$, $P=0{\cdot}105$; difference 41 per cent, 95 per cent confidence interval 10–73 per cent). At the end of follow-up, six patients (32 per cent) were disease free in the podophyllin group compared with 13 (72 per cent) in the scissor excision group ($\chi^2=4{\cdot}6$, d.f. $=1$, $P=0{\cdot}03$; difference 40 per cent, 95 per cent confidence interval 11–70 per cent) Podophyllin treatment required multiple weekly applications (median 4, range 3–5), whereas surgical treatment was completed in one session in 16 patients and two sessions in two patients. There were no

0007-1323/89/101067-02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

documented postoperative complications and none of the patients had anal canal scarring and/or stenosis or required the use of an anal dilator.

In the surgical group, 11 patients experienced pain and/or discomfort which required analgesia, compared with five patients in the podophyllin-treated group. One patient had skin burns in the podophyllin group. None of the side-effects were severe enough to warrant cessation of treatment, and pain responded to oral analgesia (paracetamol) in all cases. Sixteen (89 per cent) of the patients treated by surgery were satisfied with their treatment whereas only nine (47 per cent) of the patients treated with podophyllin were satisfied.

Discussion

Condylomata acuminata represent an important sexually transmitted disease[2,3]. Untreated lesions are most likely to persist for a long time, and give rise to distressing symptoms of perianal discomfort, irritation and occasional bleeding Rarely patients may have spontaneous regression[7] There is evidence that malignant changes can occur in these lesions[8,9] and that human papillomavirus is associated with genital and anal carcinomas[1]. There is therefore a need for effective therapy.

The factors affecting the outcome of this disease are poorly understood. The role of host immunity is suggested by the extensive refractory disease associated with immunosuppression and the 20 per cent rate of spontaneous remission in healthy subjects during the first year of infection[7]. Conventional therapy involves destruction of warty tissue with topical drugs or surgery. Recurrences are frequent, probably due to subclinical infection, and it is not clear if a virological cure is ever achieved in any patient. Existing studies are not comparable in patient selection, methods used to monitor response, and follow-up. Local application of podophyllin[5], 5-fluorouracil[10], thiotepa[11] and colchicine[12] produces variable results. Topical drugs usually give incomplete clearance in some patients at initial therapy and high recurrence rates. Surgical treatment with cryosurgery[13], electrocautery[14] and laser[15] may be more effective but these methods are painful and may produce scarring. Laser therapy is costly and not readily available. Scissor excision of the lesions offers the advantage of preserving the small but healthy skin bridges between the warts, thus promoting healing without scarring.

Thomson and Grace[4] reported a 1-year recurrence rate of 39 per cent in a non-randomized study of 75 patients with perianal and anal warts treated by scissor excision. The lower recurrence rates in this study and in others[16,17] may be because of differences in the study population.

In this study, the only side-effects detected were perianal skin burns and pain, which responded to paracetamol in all cases. The higher incidence of pain in the surgical group is to be expected and is in agreement with the findings of Jensen[16]. The low incidence of chemical skin burns in the podophyllin-treated group may be due to the careful application of the drug, avoiding the adjacent skin, and the graded time for which the preparation was left on the lesions[5].

This study demonstrates that scissor excision is a safe method of treatment of perianal condylomata acuminata and produces faster clearance and lower recurrence rates than local application of 25 per cent podophyllin. Our current approach to therapy seems irrational as condyloma acuminatum represents a viral infection of both abnormal and normal appearing epithelium. Antiviral drugs and immune modulators might be a more effective therapy. Interferons show promise[18,19], but their efficacy has been modest and no greater than that of surgery[17]. An effective treatment for condylomata acuminata remains elusive, but a combination of local removal (e.g. surgical excision) and adjuvant therapy (e.g. interferon) may be the answer.

Mr G. A. Pritchard

Excess dietary fat has been identified as a risk factor in the development of human breast carcinoma. However, the quality of fat may be more important than the overall quantity. We have studied the growth of human MCF7 breast carcinoma xenografts in athymic mice treated with dietary supplements of N-6 and N-3 series essential fatty acids given as natural preparations of evening primrose oil and fish oil. Olive oil and normal laboratory diet lacking the essential fatty acids served as controls. Animals treated with essential fatty acids developed tumours which were significantly smaller than both control groups (Mann–Whitney U test, $P<0{\cdot}001$). Median tumour weights according to diet were: evening primrose oil, 133 mg; fish oil, 70 mg; olive oil, 212 mg, and control, 270 mg. Nutritional intervention to increase the proportion of essential fatty acids in the diet may have a role in the management of breast carcinoma.

Keywords: Breast carcinoma, diet, prevention, essential fatty acids

The aetiology of human breast cancer is poorly understood. It is known that an interplay between heredity and environmental factors initiate and/or promote the disease. Factors associated with high risk have been identified as family history, menstrual history, sex hormone levels, viral infection and previous benign disease. Diet is also implicated in the pathogenesis of breast cancer. This is based on the existence of a widely varying incidence of breast cancer throughout the world which strongly correlates with the amount of fat eaten[1]. Breast cancer is common in western Europe and North America where some 140 g of fat are consumed daily (40 per cent of total calories or 20 per cent by weight) which is some five times higher than the traditional Japanese diet based on rice and seafood. Corresponding to this difference in fat intake, the European countries have an incidence of breast cancer three or four times higher than that found in Japan and Asia.

Circumstantial evidence provided by epidemiological studies is further supported by laboratory animal models of fat and breast cancer. These have repeatedly shown over the past 40 years that high levels of dietary fat, in the order of 20 per cent by weight or 40 per cent by calories which mimic the human diet, promote mammary tumour growth in rats and mice[2–4]. This finding holds true regardless of how the tumour is initiated, whether spontaneous[2,4], chemically induced by nitrosomethylurea or dimethylbenzanthracene[5], solid tumour allografts[6] or by irradiation[6,7]. The crucial threshold for tumour promotion seems to be about 10–20 per cent by weight. Numerous fats and oils have been studied and found to promote tumour growth.

However, recent interest has turned to a singular subgroup of lipids, the essential fatty acids, and it appears that they may have antitumour properties. Essential fatty acids are characterized by the presence of several double bonds in the carbon skeleton and are essential dietary requirements, rather like vitamins, because they cannot be synthesized *de novo* in the human body. The N-6 series commencing with linoleic acid are derived from plant sources and the N-3 series from fish oils. They are important structural components of all cell membranes and give rise to a variety of intermediates such as prostaglandins and leukotrienes and are thought to have wide-ranging influences on the immune system, autocrine–paracrine growth regulation and the mediation of inflammation. Linoleic acid is present in many of the polyunsaturated vegetable oils but γ-linolenic acid is relatively scarce, being found in abundance in relatively few forms such as evening primrose oil, blackcurrant seed oil and borage. Deficiency of the essential fatty acids in rodents is characterized by weight loss, dermatitis, sterility, increased susceptibility to infection and premature death[8]. Human beings on long-term parenteral nutrition lacking these essential fatty acids will also develop dermatitis which can be corrected by the supplementation of γ-linolenic acid[9].

Of greater interest is the recent finding that the essential fatty acids might have antitumour properties. A South African group has been foremost in testing essential fatty acids against numerous human cancers *in vitro*. They have shown that γ-linolenic acid can inhibit squamous oesophageal carcinoma, hepatoma, osteogenic sarcoma and laryngeal carcinoma cells without harming normal bovine kidney cells[10–13]. A Canadian group added to the growing list of cancer cell types in showing that human breast adenocarcinoma ZR751, lung A549 and prostatic carcinoma PC3 could be killed or inhibited by the essential fatty acids linoleic, γ-linolenic, arachidonic, eicosapentaenoic and docosahexaenoic acids at concentration of 20 μg/ml[14].

The purpose of this study was to investigate the role of essential fatty acid dietary supplements in the growth of a human breast carcinoma cell line *in vivo* in an animal model. Diets rich in N-6 or N-3 essential fatty acids were compared with controls lacking those essential fatty acids

Materials and methods

Animals

MF1 nu/nu/ola athymic mice were obtained from Harlan Olac, Bicester, UK and subsequently bred in our animal unit Mice were housed in groups of three in polycarbonate cages fitted with filter lids. The mice were maintained in a dedicated, clean isolation unit. Room temperature was controlled at 24°C and 12-h light and dark periods alternated.

Cell cultures

The MCF7 cell line was used as an example of human breast carcinoma It is an oestrogen-dependent cell line derived from the malignant pleural effusion of a postmenopausal woman with breast carcinoma[15]. Normal breast fibroblasts were derived from samples of breast tissue obtained from women undergoing surgery for benign breast disease. Tissue was enzymatically disassociated and separated into cell types by gravity sedimentation as described elsewhere[16]. Cells were maintained in monolayer tissue culture in RPMI 1640 medium (Gibco Ltd., Paisley, UK) supplemented with 10 per cent fetal calf serum (Gibco Ltd), human monocomponent insulin 120 units/l (Novo Industries, Romford, UK) hydrocortisone 10 mg/l (Sigma Chemical Company Ltd , Poole, UK), benzylpenicillin 60 mg/l (Glaxo Laboratories Ltd., Greenford, UK), streptomycin 100 mg/l (Evans Medical Ltd., Dunstable, UK) and amphotericin 2 mg/l (E. R Squibb Ltd., Hounslow, UK) Cultures were maintained at 37°C in an atmosphere of humidified air enriched with 5 per cent carbon dioxide.

Tumour cell inoculations

The method of Horgan *et al.*[16] was used: MCF7 and fibroblast cells were trypsinized from culture flasks. Cell viability was >95 per cent as assessed by trypan blue exclusion. Cells were counted in a haemocytometer. Two million MCF7 cells mixed with two million fibroblasts were suspended in 100 µl culture medium and injected into the right hind quarter mammary fat pad of anaesthetized female athymic mice that were 6–8 weeks old. An oestradiol pellet was inserted subcutaneously on the dorsum of each mouse to meet the hormone dependence of the MCF7 cell line.

Diets

Mice were divided into four dietary groups

Group 1: Control mice (n = *24*). These mice received a stock commercial rodent diet (Pilsbury Ltd., Birmingham, UK) which contains 4 per cent by weight total lipid of which 1·5 per cent is linoleic acid and 0·08 per cent γ-linolenic acid.

Group 2. Olive oil 10 per cent weight for weight supplement (n = *24*). This group provided an additional control as olive oil contains no essential fatty acids but 65 per cent oleic acid and 14 per cent linoleic acid

Group 3 Evening primrose oil 10 per cent weight for weight supplement (n = *24*) Evening primrose oil is one of the richest known sources of γ-linolenic acid, 9 per cent weight for weight and linoleic acid, 70 per cent weight for weight.

Group 4 Fish oil 10 per cent weight for weight supplement (n = *24*). Fish oil contains N-3 series essential fatty acids, eicosapentaenoic acid 28 per cent weight for weight and docosahexaenoic acid 5 per cent weight for weight

The control diet pellets were ground to crumbs and thoroughly mixed with the chosen oil in a domestic foodmixer. Diet was freshly prepared every 5 days and stored in air tight boxes at 4°C. A surfeit of diet was available *ad libitum* to the mice and replenished daily. Olive oil, evening primrose oil and fish oil were donated by Scotia Pharmaceuticals, Guildford, UK

Experimental protocol

Athymic mice were weaned and maintained on normal diet until they were 6–8 weeks old. They were then started on the appropriate diet for 1 week in an effort to stabilize tissue levels with the new fatty acids. MCF7 fibroblast cell inoculations were given in the mammary fat pad. Over the ensuing weeks the liquid blister was absorbed and was replaced by a solid tumour mass Five weeks later the animals were killed with an overdose of ether. Tumours were dissected out from the membranous fat pad and weighed; they were either fixed in formalin for histological examination or snap-frozen in liquid nitrogen for subsequent fatty acid analysis. The frozen tumours, identified only by a code number, were shipped to Scotia Research Institute, Kentville, Nova Scotia; the fatty acids were extracted by the method of Folch *et al*[17] and analysed by gas liquid chromatography as described elsewhere[18].

Data analysis

Tumour weights and mouse body-weights were described non-parametrically by median and interquartile range. The Mann–Whitney *U* test was used for comparison of the data. Results were accepted as statistically significant when $2P<0{\cdot}05$

Results

All 96 mice in the four dietary groups remained healthy during the course of the experiment without overt signs of infection and no premature deaths. Each mouse consumed about 5 g diet daily and all mice gained body-weight. There was no significant difference in the amount of body-weight gained, about 4 g, by the mice in the various dietary groups (*Table 1*). The tumour model worked well with 92 of 96 mice developing a solid tumour. Tumours grew as discrete solid nodules and were readily identified and removed from the filamentous, connective adipose tissue of the mammary fat pad. On histological examination the MCF7 tumours were seen to be highly cellular consisting of epithelioid cells arranged in sheets in a fine, fibrous stroma The inclusion of fibroblasts with the MCF7 cells in the inoculum did not produce fibrous overgrowth. Tumours taken from mice which were fed the various lipid diets were identical both macroscopically and microscopically.

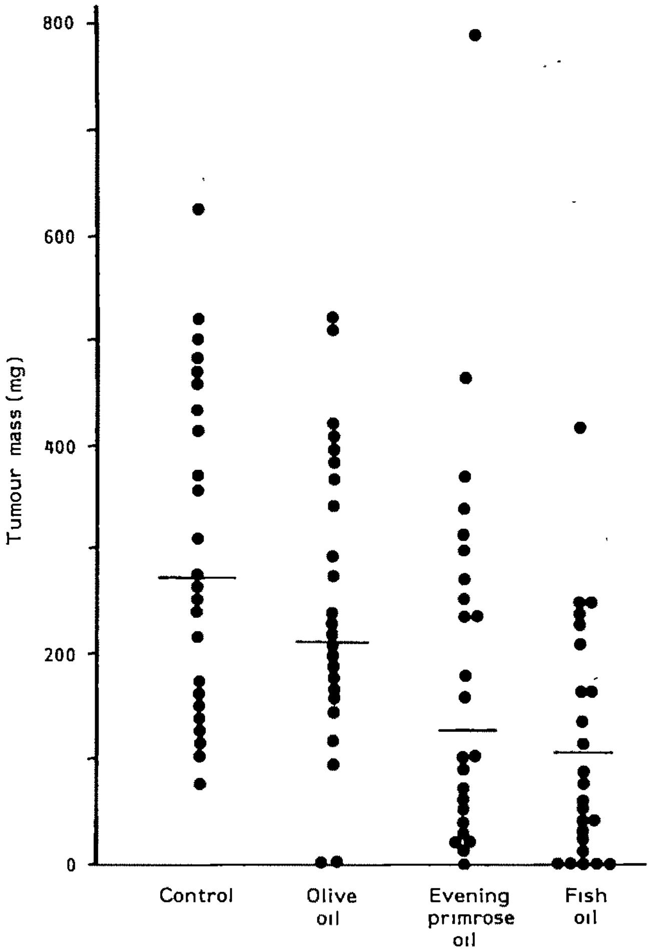

Figure 1 *Scattergrams showing individual MCF7 tumour weights according to diet. Bars indicate median values*

The range of tumour weights was 0–795 mg. Individual tumour weights according to diet are shown as scattergrams in *Figure 1*. A descriptive non-parametric summary of tumour weights is shown in *Table 2*. Those animals fed the usual laboratory diet as controls developed tumours with a median weight 270·5 mg. Feeding a 10 per cent olive oil supplement, with virtually no additional fatty acid, did not influence tumour growth in any way compared with controls ($2P = 0{\cdot}34$) with a median tumour weight of 212 mg. Feeding the mice supplements of N-6 or N-3 series essential fatty acids as primrose oil and fish oil significantly inhibited tumour growth. Mice treated with 10 per cent evening primrose oil developed tumours which were half the size of controls (median tumour weight 133 mg *versus* 270 mg, $2P<0{\cdot}009$). The fish oil

dietary group developed tumours of median weight 70 mg, again significantly smaller than control, $2P < 0{\cdot}001$. There was no difference in the efficacy of tumour inhibition achieved by either primrose oil or fish oil ($2P = 0{\cdot}09$).

Tumour fatty acids

Fifteen tumours from each dietary group were analysed for dietary fatty acid content: the results are shown in *Table 3*. Tumours taken from mice fed the control diet were rich in unsaturated and monounsaturated fatty acids, chiefly palmitic, palmitoleic and oleic acids. Supplementation with all three polyunsaturated lipids, olive oil, primrose oil and fish oil, reduced the proportion of unsaturated fatty acids to polyunsaturated fatty acids. The exact balance of fatty acids reflected the particular diet. Thus, olive oil which comprises 65 per cent oleic acid increased the amount of oleic acid appearing in the tumour tissue. Evening primrose oil diet rich in the N-6 series essential fatty acids produced a significant rise in the tumour levels of linoleic, γ-linolenic, dihomo-γ-linolenic and arachidonic acids. Similarly, fish oil containing the N-3 series essential fatty acids resulted in the accumulation of those particular fatty acids, eicosapentaenoic and docosahexaenoic acids.

Discussion

The evidence of an epidemiological association between dietary fat and the development of breast cancer is strong and is supported by numerous animal models. It has been repeatedly shown that high levels of dietary fat, >10 per cent by weight, promote mammary tumour development whereas very low fat diets, <5 per cent by weight, and particularly fat-free diets inhibit tumour growth[2,5–7,19–22]. Unfortunately, however, it is unrealistic to expect humans to eat a totally fat-free diet, however beneficial. None the less, eminent American authorities have already advocated a drastic reduction in the amount of fat consumed from 40 to 20 per cent of calories[23,24]. With the recent realization that the balance of fatty acids may be more important than the total quantity, the current experiments have attempted to maintain an acceptable level of fat in the diet yet increase the proportion of polyunsaturates and essential fatty acids. Several independent groups have shown that the N-6 series essential fatty acids in evening primrose oil and N-3 essential fatty acids in menhaden marine oil (Zapata Haynie Corporation, Reedville, USA) and *Maxepa* fish oil (Duncan, Flockhart and Company Ltd., Greenford, UK) will significantly inhibit the growth of species-specific mammary tumours induced in rats and mice[25–30].

The advantage of the presently described athymic mouse model is that it allows an *ex vivo–in vivo* assessment of human breast carcinoma to these lipids. Athymic mice have a congenital absence of the thymus gland and hence lack T cell mediated immunity and are unable to reject foreign species' xenografts. This is the first report of a human breast carcinoma cell line being susceptible to treatment with essential fatty acids. Both evening primrose oil and fish oil were equally effective in limiting tumour growth by 51 per cent and 74 per cent respectively of control growth. Olive oil, which is devoid of essential fatty acids, had no effect on tumour growth. Two previous studies[25,26] found that 200 μl evening primrose oil daily given either by stomach tube or parenteral injection restricted rat R3230AC mammary tumour growth by 25–50 per cent. However, this dose level is difficult to extrapolate to possible human use. The advantage of using a specified 10 per cent by weight dose level is that some relevance to human doses may be made. A fat level of 10 per cent by weight provides 20 per cent of total calories and in human terms some 50 to 60 ml of primrose and fish oil would meet this requirement. This seems a somewhat high dose but is none the less practical, and improved pharmacological preparations of highly concentrated fatty acids may make delivery even simpler in future. There are now several pointers that essential fatty acids have antitumour properties but the mechanism of their effect is poorly understood. The present study showed that the N-6 and N-3 series essential fatty acids accumulated in the relevant tumours but it is unknown whether structural changes in cell membranes were responsible for the change in biological properties or whether the fatty acids simply acted as substrates for other intermediates to exert the effect.

There are several hypotheses to explain the possible mode of action of essential fatty acids. The essential fatty acids are obligate precursors of prostaglandins of the 1, 2, 3 and 4 series and it is well recognized that prostaglandins can influence malignant cell behaviour. For example, many cancers produce excessive amounts of the 2 series prostaglandins and yet are unable to manufacture prostaglandin E1[31], which is itself tumoricidal to DMBA-induced mammary tumours *in vitro*[32]. Some studies infer an opposing tumour-promoting action to certain prostaglandins because anti-inflammatory drugs such as flurbiprofen and indomethacin, which inhibit prostaglandin synthesis, are able to restrict tumour growth in mice[33] and even counteract the tumorigenic effect of a high fat diet[34]. Whilst the action of essential fatty acids may be expressed via derived prostaglandin products it is difficult to predict or control which of the many prostaglandin classes would gain by simple provision of additional dietary substrate.

Figure 2 shows a flowchart of the synthesis of N-3, N-6 and N-9 polyunsaturated fatty acids. One enzyme, Δ-6-desaturase, catalyses the same crucial desaturation step in all three pathways[35]. Many, if not all, transformed and malignant cells lose this enzyme[36,37] and consequently the intracellular synthesis of longer chain polyunsaturated fatty acids is arrested. Further support for this enzyme deletion is found in the work of Wood *et al.*[38] who described a fall in the stearic:oleic acid ratio in red cell membranes of patients suffering from a variety of cancers. This was considered to be a non-specific marker for cancer but no explanation was offered about the mechanism. In the light of Δ-6-desaturase enzyme deletion it can be seen from *Figure 2* that whilst stearic acid may be converted to oleic

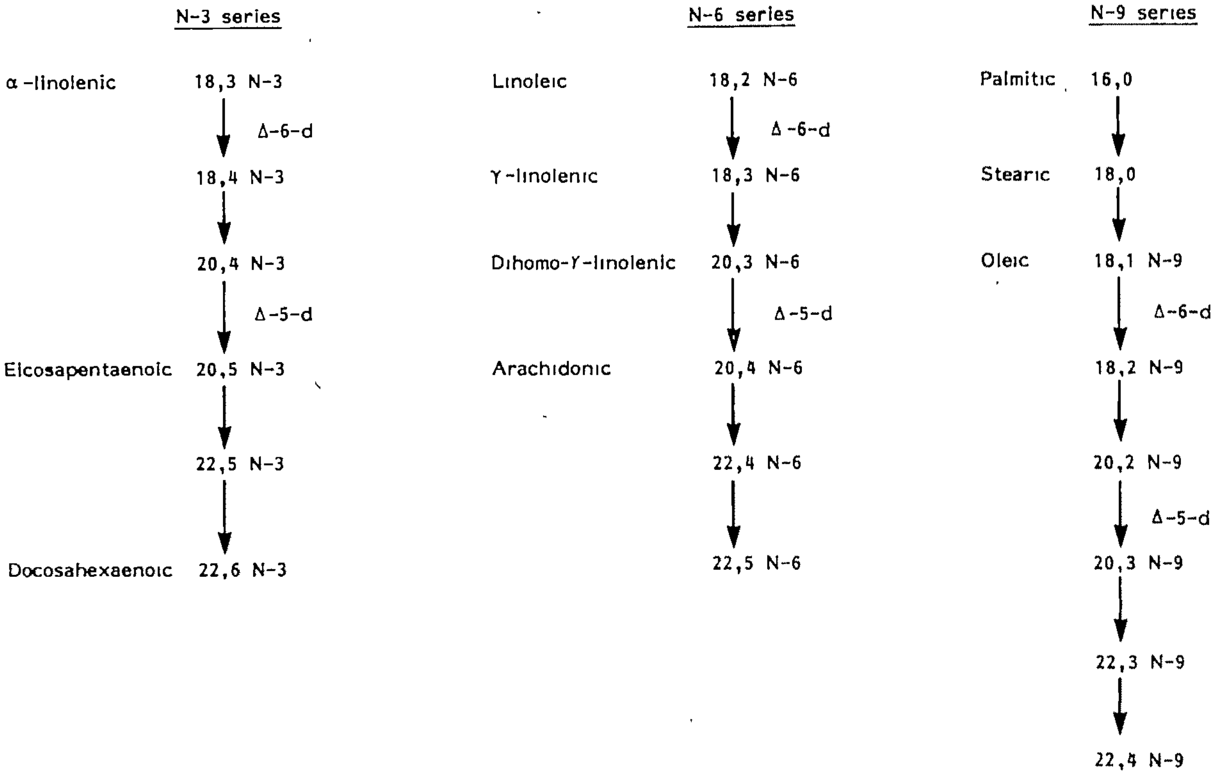

Figure 2 *Biosynthesis of N-3, N-6 and N-9 series polyunsaturated fatty acids. Δ-5-d and Δ-6-d represent the desaturase enzymes creating double bonds at the 5 and 6 carbon positions*

acid the enzyme deletion will prevent further metabolism of oleic acid. Oleic acid will therefore accumulate and the ratio of stearic to oleic acid will fall. The effects of the Δ-6-desaturase enzyme deletion can theoretically be overcome by exogenous supply of γ-linolenic and eicosapentaenoic acids which are capable of entering the pathways at later stages. The restored metabolic function might go some way to restoring normal regulation of cellular activity.

Polyunsaturated fatty acids and essential fatty acids containing several double bonds are unstable molecules and are readily oxidized by non-specific and specific lipoxygenase and cyclo-oxygenase enzyme systems to yield free lipid radicals and peroxides which are toxic to cells. Horrobin's group reported that the human breast adenocarcinoma ZR751 was killed by treatment with essential fatty acids *in vitro* and they found increased levels of lipid peroxides and superoxide anions within the cells as shown by nitro blue tetrazolium reduction and the high content of thiobarbituric acid reactive material[39]. Vitamin E, an antioxidant which scavenges free radicals, blocked this cytotoxic effect. Yet another mechanism is the subtle regulation of cell growth at a local level. Lippman's group have shown that oestrogen and progestin hormones act on breast cancer cells as mitogens by inducing the secretion of a variety of peptides, such as insulin-like growth factor 1, which have a role as autocrine and paracrine growth regulators[40]. Some of these growth regulatory factors are themselves essential fatty acids[41]. Progestins inhibit MCF7 growth *in vitro* by inducing a 72 kilodalton protein which has identical biochemical properties to the enzyme fatty acid synthetase[42].

Thus it can be seen that there is a logical explanation for the involvement of fats in breast carcinogenesis. The National Cancer Institute in the USA is already so convinced of the circumstantial evidence linking high fat diets and breast carcinogenesis that they have initiated studies of dietary intervention in women with advanced breast cancer and also proposed low fat diets as adjuvant therapy for women at risk of developing the disease[24]. On the basis of the present work we would suggest that the proposed reduction of total fat does not go far enough. We would advocate that the balance of fatty acids in the diet must be altered to increase the proportion of essential fatty acids. This might be achieved by simple changes in dietary practice to consume more sea food and reduce the amount of animal fat eaten or take the form of dietary supplements of specific essential fatty acids. Dietary intervention may well prove to be a useful adjunct to existing therapies in the treatment of breast cancer.

Postsplenectomy sepsis

J. H. F. Shaw and C. G. Print

University Department of Surgery, Auckland Hospital, Auckland, New Zealand

Correspondence to:
Professor J. H. F. Shaw

This review examines the infectious consequences of elective and emergency splenectomy, highlighting the importance of infection with Streptococcus pneumoniae. *The influence of splenectomy on the immune system is discussed and the efficacy of vaccines in preventing postsplenectomy sepsis is reviewed. The value of alternative methods of preventing postsplenectomy sepsis is considered.*

Keywords: Splenectomy, infection, pneumococcal vaccine

Despite the increasing use of splenic conservation emergency splenectomy is still performed frequently, and elective splenectomy, although now rarely used to stage lymphoma, is still performed for giant splenomegaly, hairy-cell leukaemia and idiopathic thrombocytopenic purpura. As a result, postsplenectomy sepsis remains an important topic.

The clinical appearance of postsplenectomy infection varies from a mild pneumonia to a fatal overwhelming sepsis[1–10] and clinicians have attempted to reduce such infections by immunizing against the common infecting organisms, administering prophylactic antibiotics and, more recently, by employing splenic conservation. However, despite widespread use of prophylactic antibiotics and capsular polysaccharide vaccines, there is extensive discussion over many aspects of their use, and the place of partial splenectomy and/or splenic autotransplantation is unclear.

In order to formulate guidelines for the prevention of infection in the asplenic patient we have reviewed the available literature and attempted to answer the following questions: (1) what are the infectious consequences of splenectomy; (2) how does removal of the spleen alter the immune system, and how effective are vaccines in preventing postsplenectomy infection; (3) are other methods of sepsis prophylaxis worthwhile?

What are the infectious consequences of splenectomy?

Characteristics of postsplenectomy infection

Ellison and Fabri[1] list the complications of splenectomy as respiratory complications, haemorrhage, splenic abscess, injury to adjacent structures, thrombosis and thrombocytosis, postsplenectomy infection and unexplained fever. In addition they suggest that 'postsplenectomy infection represents a spectrum of infectious processes. In its mildest form lobar pneumonia may occur while its more severe form is that of overwhelming and fatal infection, the onset of which is often subtle yet sudden, and the focus often obscure.' Alternatively, postsplenectomy sepsis has been defined by Singer[2] as 'septicaemia, meningitis or pneumonia, usually fulminant, but not always fatal, occurring days to years after removal of the spleen.'

Interest in the phenomenon of postsplenectomy sepsis was aroused by the observations of King and Shumacker[3] in 1953. They described five cases of fulminant sepsis in infants who had undergone splenectomy for congenital spherocytosis. Since then various degrees of severity have been described but commonly postsplenectomy sepsis presents as an overwhelming infection with multiorgan failure[4]. Diamond[5] in 1969 first coined the term 'overwhelming postsplenectomy infection' (OPSI) to describe a fulminant bacteraemia which can lead to a rapid demise. The following characteristics of OPSI were described by Van Wyck[6] in 1983: extraordinarily fulminant course, frequent absence of a septic focus, bacteraemia, coma, shock, consumptive coagulopathy and adrenal haemorrhage (Waterhouse–Friderichsen syndrome). An interesting feature is the high number of bacteria found in the blood of these patients. More than one million bacteria per millilitre are often found in the blood of splenectomized septic individuals, while non-splenectomized septic individuals[7] rarely show more than one thousand organisms per millilitre.

Incidence and mortality of postsplenectomy infection

Estimates of the frequency of occurrence and the mortality associated with postsplenectomy sepsis vary. The reason for this variability can, to some degree, be understood when the differences between the various studies are appreciated Firstly, postsplenectomy sepsis is a rare event, so large patient populations with large control groups are needed to estimate the incidence reliably. Secondly, the definitions of postsplenectomy sepsis and OPSI vary from study to study. Thirdly, postsplenectomy sepsis can occur many years after splenectomy and, as Frank and Neu[8] suggest, studies with short follow-up may underestimate its frequency. Lastly, the incidence of sepsis varies with age, underlying disease process and the indication for splenectomy so to be useful any individual study must stratify for these variables.

O'Neal and McDonald[9] observed 256 adult splenectomy patients for an average of 45 months and found that 2·7 per cent developed postsplenectomy sepsis; they estimated that death from sepsis in these asplenic adults was 540 times as prevalent as death due to sepsis in the population at large. A comparable incidence of postsplenectomy infection was found by Hays *et al.*[10] in a population of 234 lymphoma patients who had undergone splenectomy as part of staging laparotomy. Over a mean surveillance period of 3·8 years there were four episodes of bacterial sepsis with positive blood cultures (1·7 per cent chance of sepsis), despite the fact that 83 per cent of the patients had received pneumococcal vaccination and 74 per cent had received prophylactic antibiotics.

Green *et al.*[11] however suggest that postsplenectomy sepsis is more common. They followed 144 postsplenectomy patients for an average of 61 months; 9 per cent developed major sepsis requiring hospitalization and 30 per cent developed minor septic complications. In contrast, Chaikof and McCabe[12] found that postsplenectomy sepsis was very uncommon. They reviewed 776 splenectomized patients over a mean follow-up period of 8·4 years. The incidence of fatal OPSI in their series was 3·7 per cent for children and 0·3 per cent for adults. This incidence seems low compared with some similar studies but Strauch[13] points out that the average age of adults in this series was 57 years and 127 adults in this series were lost to follow-up. These factors may explain the apparent low incidence of sepsis in this study.

Schwartz *et al.*[14] reviewed 193 postsplenectomy adults who were otherwise healthy with follow-up averaging 5·6 years. In this series the risk of serious infection (requiring hospitalization) varied with the indication for splenectomy. The overall rate of infection was 7·1 infections per 100 person-years of follow-up.

0007-1323/89/101074–08$3 00 © 1989 Butterworth & Co (Publishers) Ltd

The incidence (per 100 person-years) for the different splenectomy indications was: trauma, 3·3; primary splenic disease, 4·0; haematological diseases, 6·5; incidental to abdominal surgery for cancer, 16·6; and incidental to other forms of abdominal surgery, 9.6. Platt[15] considered this study valuable as it is free from bias, has nearly complete follow-up, and 'The low observed rate does not contradict reports of excess risk of pneumococcal sepsis after splenectomy, but does suggest that the absolute increase in attack rates is not great.'

Another approach to assess postsplenectomy infection was that of Robinette and Fraumeni[16]. They followed 740 servicemen, splenectomized for trauma in the 1939–45 war and demonstrated a significantly increased mortality rate from pneumonia and heart disease in these patients compared with individuals having intact spleens.

Despite the problems discussed above, multistudy reviews of OPSI do have the advantage of large numbers of patients. One such review is that of Singer[2] who reviewed 2795 postsplenectomy patients (from 24 series) and found that the overall incidence of sepsis was 4·2 per cent with an overall mortality rate of 2·5 per cent. As in the study of Schwartz *et al.*[14], risk varied with the indication for splenectomy; for the 921 patients who underwent splenectomy for trauma or incidental to other surgery, the incidence was 1·6 per cent and the mortality rate was 0·7 per cent.

Another review of 3430 collected cases[8] in 1981 assessed splenectomized patients under 17 years of age, and found an overall incidence of infection of 5 per cent. The highest incidence was in patients with congenital or acquired anaemias, portal hypertension, or lymphoreticular tumours. Overall for adults and children combined, sepsis occurred in 3·9 per cent with a mortality rate of 2·4 per cent. In a multistudy review by Ellison and Fabri[1] an overall incidence of postsplenectomy sepsis of 3·8 per cent was found; for paediatric patients the incidence was 4 per cent and the mortality rate was 1·8 per cent, while in adults the corresponding values were 1·9 per cent and 1·1 per cent respectively. Overall they concluded that the patients had a 40-fold increased risk of infection and a 17-fold increased risk of fatal sepsis.

What other factors influence the risk of postsplenectomy infection?

In some instances factors other than splenectomy seem to be more important in altering the risk of sepsis[13,17–19]. The risk of sepsis varies with the indication for splenectomy and in some circumstances splenectomy *per se* has a lesser part in predisposing to sepsis than the underlying disease. This is particularly true for patients with Hodgkin's disease. Donaldson *et al.*[20] in an assessment of 181 Hodgkin's patients, about half of whom had had splenectomy, could find no difference in infection or mortality rates between the two groups. Similarly, Keel and Bennett[21] compared 56 splenectomized patients with Hodgkin's disease with 28 non-splenectomized patients also with Hodgkin's disease. They found that for stage 2 and 3 disease splenectomy *per se* did not increase the risk of infection, and that the use of chemotherapy was a more important predisposing factor.

Whatever the relative importance of splenectomy *per se* compared with the underlying disease process, postsplenectomy patients are at an increased risk of sepsis. Balfanz *et al.*[22] point out that while the incidence of postsplenectomy infection is low, its mortality is high, making it a problem of major concern. Ellison and Fabri[1] state that 'Postsplenectomy sepsis in the adult having splenectomy for injury seems to be a rare event for which there is not sufficient solid evidence to establish an exact risk.'

Does splenectomy alter the susceptibility to infection in experimental animals?

Coil *et al.*[23] in a prospective study, showed that splenectomized mice were more susceptible to pneumococcal infection than intact controls, while Leung *et al.*[24] showed asplenic rats were more susceptible to *Pneumococcus* than controls. Similar results have also been found with susceptibility to coliform or *Haemophilus influenzae* infections[25], although Loggie and Hinchey[18] found that survival of mice after meningococcal challenge was similar in control and asplenic animals.

When does infection occur relative to splenectomy?

Fatal sepsis has been reported up to 30 years after splenectomy[1], but Schwartz *et al.*[14] found that most septic events occurred in the first year after operation. Similarly, Ellison and Fabri[1] found that 20 per cent of cases of fatal sepsis occur in the first 6 months after splenectomy and 60 per cent occur within 2 years. They also point out that the shorter the interval between splenectomy and sepsis, the greater the risk of mortality. A different perspective has, however, been put forward by Van Wych[6]. In his collection of 55 cases of OPSI less than 30 per cent occurred within 3 years of splenectomy.

Which age-group is at most risk from postsplenectomy sepsis?

The problem of postsplenectomy infection was first recognized in children and most series demonstrate a higher incidence in children than in adults. For example, Ellison and Fabri[1] found that postsplenectomy sepsis affected children twice as often as adults regardless of the reason for splenectomy, and that children also had a higher risk of mortality. A similarly increased risk in children was also described by Chaikof and McCabe[12] who found an 11-fold increase in risk of postsplenectomy infection in children compared with adults (incidence of 3·8 *versus* 0·3). Ellison and Fabri[1] also highlight the fact that the mortality rate is higher in children, concluding that postsplenectomy sepsis is fatal in over 50 per cent of paediatric cases but in less than one-third of adult cases.

The causative organisms in postsplenectomy sepsis

According to Ellison and Fabri[1] over 50 per cent of cases of postsplenectomy sepsis involve pneumococcal infection, other bacteria involved in descending order of frequency being *H. influenzae*, *Neisseria meningitidis*, β-haemolytic streptococci, *Escherichia coli* and *Pseudomonas* species Brigden[26] stressed that the encapsulated *Pneumococcus*, *Meningococcus* and *Haemophilus* species are the most frequently involved bacteria, a finding confirmed by other investigators[27]. It is also apparent that certain subtypes of the encapsulated organisms are more frequently involved. Gopal and Bisno[28] suggest that a limited number of pneumococcal serotypes predominate in postsplenectomy sepsis, in particular type 12, while Kafidi and Rotschafer[29] indicate that virtually all invasive *H. influenzae* disease occurring in the asplenic host is due to *H. influenzae* type b, and that most *N. meningitidis* infection results from groups A, B, C, Y and W135.

There are anecdotal reports of other organisms causing fulminating postsplenectomy infection, including *N. gonorrhoeae*[30], DF-2 bacterium[31], *Babesia* species[8], as well as cytomegalovirus[5], herpes[32] and influenza virus[33]. In addition, the Papua New Guinea Splenic Injury Group[34] indicate that splenectomy predisposes to malaria.

How does splenectomy alter the immune system and how effective are vaccines in preventing postsplenectomy infection?

How does removal of the spleen alter immune function?

In 1985 Brigden[26] stated that 'The mechanisms of defence against pneumococcal infection in humans are complex and include: the presence of adequate numbers of leucocytes, the action of type-specific antibody, the state of the host's reticuloendothelial system, the host's underlying illness, and medications given as therapy.' The spleen plays an important part in these defences and Ellison and Fabri[1] identified three components of the reticuloendothelial function of the spleen.

Phagocytosis and clearance of micro-organisms. Several aspects of phagocytosis and clearance of organisms are altered by splenectomy. Splenectomized rats have significantly impaired clearance of *Pneumococcus* compared with normal animals, and this is probably because the liver can only remove well opsonized bacteria from the blood, poorly opsonized bacteria being cleared only by the spleen[35]. Delayed type hypersensitivity reaction to *Bacillus* Calmette-Guérin vaccine in animals is reduced after splenectomy[36], as is amplifier T cell activity[37] and the production of memory cells[38]. The spleen also removes parasites, such as malarial organisms, from red blood cells and, as a consequence, splenectomy may reduce the host's defences[34].

Elaboration of a specific immune response. After exposure to an antigen the IgM antibody response is initiated in the white pulp of the spleen and after splenectomy antibody production and, therefore, opsonization of bacteria are likely to be reduced[8]. Frank and Neu[8] point out that encapsulated organisms must be opsonized before phagocytosis can occur. As a result there are two major reasons for reduced clearance of bacteria from the blood after splenectomy. Firstly, asplenic patients lack the splenic phagocytes capable of clearing bacteria coated with only small amounts of immunoglobulin and, secondly, they are unable to mount a sufficient antibody response to enable liver macrophages to overcome this defect[29,39]. Sullivan *et al.*[40] in 1978 also showed that after splenectomy the antibody subclass produced in response to pneumococcal vaccine did not switch appropriately from the initial IgM response to the later IgG response, as seen in normal individuals.

The production of opsonins. Eichner[41] discusses two proteins that the spleen produces which serve as opsonins: tuftsin, a tetrapeptide that promotes phagocytosis in polymorphonuclear leucocytes, and properdin, a vital component of the alternative complement pathway. Levels of both are reduced immediately after splenectomy and tuftsin deficiency has been noted up to 20 years later[8].

It was thought that deficiency of the alternative complement pathway, due to lack of properdin, might play a part in increasing the incidence of infection with encapsulated organisms after splenectomy[8]. However, this now seems unlikely as serum from asplenic patients will opsonize pneumococci as well as serum from normal patients[42], and Nielson *et al.*[43] after measuring complement titres in 85 splenectomized patients could not detect any major deficiencies. In addition, Hosea[38] states that 'The complement system has so much reserve that only after 99 per cent depletion of serum C3 are severe opsonic defects noted.' Thus it is probably not a primary defect in the complement system which predisposes to OPSI.

How effective are vaccines in preventing postsplenectomy infection?

Vaccine availability: Pneumococcal vaccine. Several vaccines against *S. pneumoniae* were evaluated in the 1920s but were abandoned when effective antibiotics became available. The current pneumococcal vaccine, Pneumovax-23 (Merck Sharp and Dohme, West Point, Pennsylvania, USA), consists of a mixture of purified capsular polysaccharides from 23 pneumococcal subtypes. Initial studies were conducted on healthy individuals with intact spleens[44,45] but more recently pneumococcal vaccine has been extensively studied in patients undergoing splenectomy.

Haemophilus vaccine. The *H. influenzae* vaccine was also first tested in populations of healthy individuals with intact spleens but unlike the pneumococcal vaccine it has not been extensively assessed in patients undergoing splenectomy Kafidi and Rotschafer[29] describe the two currently available vaccines and Peltola *et al.*[46] have demonstrated the effectiveness of *H influenzae* vaccination in a series of 50000 normal children.

Meningococcal vaccine. Kafidi and Rotschafer[29] describe a vaccine for *N. meningitidis* groups A and C which has been used for more than 10 years, but again most trials have been in healthy subjects and few series have tested its efficacy in patients undergoing splenectomy.

Antibody responses to vaccines. Some studies indicate that there is a decrease in antibody response to capsular polysaccharide vaccination after splenectomy[47] while others indicate that splenectomy does not alter antibody responsiveness[44,45]. A number of factors account for this conflict. Firstly, there is an individual variation in antibody response to vaccines; secondly, the different serotypes of vaccine induce different rates and magnitudes of antibody response; and lastly, some antibody assays are more sensitive than others[48–53].

Does splenectomy reduce the antibody response to capsular polysaccharide vaccination? The usual response of a healthy individual to pneumococcal vaccine is described as a twofold increase in type-specific antibody over a 2–3 week period[26]. In view of the changes in the immune system that occur following splenectomy it would be reasonable to expect postsplenectomy pneumococcal vaccination to be less effective than vaccination before the spleen is removed, and this is supported by the study by Di Padova *et al.*[54]. They showed that patients without spleens have an adequate early phase IgG response to pneumococcal vaccination at 7 days, and suggest that this response may be mediated by lymph nodes. However, they found that the mitogen-stimulated late phase response to pneumococcal vaccine at 21 days was impaired in asplenic patients. This finding, that the spleen has a central role in the production of the late phase antibody, confirms other reports[6,47,55] that splenectomy is associated with both a persistent deficiency of circulating B cells capable of synthesizing antipneumococcal capsular antibody and reduced IgM and IgG synthesis in peripheral blood mononuclear cells. As a result, a number of authors suggest that vaccines should be given before operation whenever possible[6,47,48,55–60]. Splenec tomy has also been shown to reduce the response to other vaccines, including *E. coli*[49].

Although most studies support the contention that pneumococcal vaccine will induce the greatest antibody response if given before splenectomy this is not to say that the reduced antibody response following vaccination performed after splenectomy will not offer some protection from sepsis. Although Perkins *et al.*[50] concede that the antibody level achieved in asplenic patients will be less than 50 per cent of that achieved in intact individuals, they suggest that the resulting antibody levels are still 'protective in most cases'.

A minority of reports conclude that splenectomy does not reduce the antibody response to capsular polysaccharide vaccination. For example, Dawes *et al.*[53] found no significant difference in antibody response to pneumococcal vaccine in rats that had undergone splenectomy, sham operation, hemisplenectomy or splenectomy with autotransplantation. Caplan *et al*[61] studied 16 patients having splenectomy for trauma and ten intact controls and concluded that if pneumococcal vaccination was administered within 72 h of operation the antibody response was not impaired. Addiego *et al.*[62] also found that untreated Hodgkin's disease patients had a similar antibody response to pneumococcal vaccination irrespective of whether the vaccine was given before or after splenectomy, and Siber *et al.*[63] found that the antibody response to pneumococcal, meningococcal and *H. influenzae* vaccines in Hodgkin's disease patients was not affected by the timing of immunization relative to splenectomy. Oldfield *et al.*[64] also came to a similar conclusion in a study comparing 21 asplenic patients with 12 controls.

How long does the antibody response to polysaccharide vaccination last? Borgono *et al.*[65] studied intact adults and showed that there was only a minor decline in antibody titre 13 months after vaccination. In a longer follow-up study in intact individuals Vela *et al.*[66] found that adults had a 50 per cent decline in pneumococcal vaccine-induced antibody titre at 3 years while children showed a similar decline after only 21 months.

Weibel *et al.*[67] found only a slight decline in antibody titres to pneumococcal vaccine 20 months after vaccination. In addition, Giebink *et al*[68] studied vaccinated asplenic children and found significant variations in the rates of decline in titre for the different capsular subtypes. Other studies indicate that antipneumococcal antibodies induced by vaccination disappear more rapidly in asplenics and in immunosuppressed and lymphoma patients[63] than in controls. It appears that the rate of decline of IgM is more rapid in asplenics than in intact controls while the IgG response declines equally in both groups[69,70].

For the meningococcal and *Haemophilus* vaccines, information on the rate of decline of vaccine induced antibody is only available for subjects with intact spleens. Kayhty *et al.*[71,72] followed several thousand healthy children vaccinated against *H. influenzae*. In infants aged less than 18 months protective titres lasted less than 6 months while in the infants aged over 18 months protective titres persisted for up to 3 years.

Vaccine responses in children. Some studies place the efficacy of pneumococcal vaccines for young children in doubt. For example, Hilleman *et al.*[73] found that intact children less than 2 years of age had a diminished antibody response to pneumococcal vaccine when compared with older children. Francke and Neu[8] came to the same conclusion and suggested that children probably do not respond adequately to any capsular vaccines until 4 years of age This latter contention is disputed by Cowan *et al.*[74] who demonstrated that some pneumococcal polysaccharide types resulted in a significant antibody response as early as 3 months of age. Furthermore, Aaberge and Heier[69] conclude that splenectomized children as old as 15 years of age have a reduced antibody response to pneumococcal vaccination when compared with the adult response.

Despite the apparent diminished antibody response to vaccination in children, some clinicians feel that it is still worth giving the pneumococcal vaccine on the off-chance that the patient gains some protection. Ammann[75] suggests that pneumococcal immunization of patients under 2 years of age is probably not harmful and could result in protection. On the other hand, Granoff[76] suggests that there is not enough information to recommend pneumococcal vaccination for children under 2 years of age. Data concerning the use of other vaccines in children are sparse but Peltola *et al.*[46] conclude that, for *H. influenzae* vaccine, the earliest age at which an adequate antibody titre can be induced is 18 months.

Other factors likely to influence the antibody response to vaccination. Many studies suggest that the underlying disease and/or its treatment may affect the antibody response to vaccination as least as much as splenectomy *per se*. Pedessen *et al.*[77] found that the antibody response to pneumococcal vaccine in 67 splenectomized patients with benign disease was not significantly different from that of 12 healthy controls with intact spleens; in comparison, five untreated splenectomized adults with malignant disease and 11 splenectomized adults receiving immunosuppressive therapy showed a significantly reduced antibody response to the vaccine. Similarly, Shildt *et al.*[78] found that patients with lymphoma treated with chemotherapy had a comparatively poor antibody response to pneumococcal vaccination. From another perspective, Shapiro and Clemens[79] conducted a case control study into the protective effect of pneumococcal vaccine and concluded that the vaccine had an overall protective efficacy of 67 per cent, while in the severely immunocompromised patients protection was almost nil.

Similar conclusions have been drawn for meningococcal vaccination. Ruben *et al.*[80] tested a bivalent meningococcal vaccine on 22 asplenic patients and 15 controls. Those whose spleens had been removed for trauma, non-lymphoid tumours or idiopathic thrombocytopenic purpura had antibody responses similar to healthy controls. However, the antibody response was reduced in patients who underwent splenectomy for lymphoid tumours, and again the IgM response was more affected than the IgG response.

It is difficult to separate the influence on the immune system of the presence of a lymphoid tumour *per se* from the effect of immunosuppressive treatment, but it appears that immunosuppressive treatment is the more important. Donaldson *et al.*[81] indicate that 'Although Hodgkin's disease may have major effects on cellular immune mechanisms, little evidence supports the theory that the disease significantly alters the ability of individuals to develop adequate humoral immunity.' They found that children who were immunized at the time of initial diagnosis, before splenectomy and subsequent immunosuppressive treatment, had a significantly better response to vaccination than children who had undergone staging and treatment. In addition, Addiego *et al.*[62] showed that pneumococcal vaccination induced a significant antibody response in virtually all patients with Hodgkin's disease, either before or after splenectomy, providing they had not commenced immunosuppressive treatment. The antibody response to vaccination was significantly reduced if chemotherapy was commenced within 10 days of immunization.

Another factor influencing the response to vaccination is genetic make-up. Ambrosino *et al.*[82] found that individuals with the genetic marker of the IgG-2 subclass had an enhanced antibody response to *H. influenzae* and meningococcal vaccines when compared with marker-negative individuals. Genetic make-up may also influence an individual's antibody response to other vaccines[52].

Neither anaesthesia nor surgery appears to influence the antibody response to vaccination. In rats vaccination immediately after anaesthesia and surgery does not reduce antibody responsiveness[83], while in man the antibody response to pneumococcal vaccine is not impaired in patients with healed traumatized spleens[70].

Do polysaccharide vaccines protect patients from pneumococcal infection? Several studies suggest that polysaccharide vaccination, in addition to inducing an antibody response, also provides *in vivo* protection from bacterial disease. For instance, Scher *et al.*[35] immunized rats with pneumococcal vaccine 2 weeks after splenectomy and found that when inoculated with *Pneumococcus* they had significantly better pneumococcal clearance than non-immunized rats. Other investigators, also using animal models, have reached similar conclusions[53], and *in vivo* human studies also show that vaccines have a protective effect. For example, Bolan *et al.*[84] found that pneumococcal vaccine effectively prevented bacteraemic pneumococcal disease in asplenic subjects providing they were fully immuno competent.

On the other hand there are a number of reports of vaccine failure. The fact that capsular polysaccharide vaccines do not eliminate postsplenectomy sepsis (rather they merely reduce its incidence) is highlighted by reports documenting sepsis despite the use of vaccination and/or prophylactic antibiotics[85–88].

Ellison and Fabri[1] point out that half the organisms causing postsplenectomy sepsis are not pneumococci and that at least 20 per cent of pneumococcal subtypes are not covered by the available vaccine. They also suggest that the incidence of various antigenic types in pneumococcal infection is changing and, as a result, the protection offered by any particular vaccine may be variable. Brigden[26] also highlights the fact that the 23-valent pneumococcal vaccine does not cover all subtypes of bacteraemic pneumococcal disease encountered in North America, and Schlaeffer *et al.*[85], after reviewing 59 cases of pneumococcal bacteraemia in patients who had received 14-valent pneumococcal vaccine, found that 32 per cent of strains of pneumococci responsible for sepsis were not present in the vaccine

There are also reports of vaccine-type pneumococcal sepsis occurring in vaccinated splenectomized patients[89]. Zarrabi and Rosner[90] studied pneumococcal sepsis and meningitis in recipients of pneumococcal vaccine and found that 21 out of 33 pneumococcal isolates in splenectomized patients were subtypes included in the vaccine. Further, 14 out of 22 pneumococcal isolates in patients who had intact spleens were vaccine serotypes.

Vaccine side-effects. In general, serious side-effects of pneumococcal vaccine are rare, with only five anaphylactic reactions per million doses administered[91]. Minor side-effects, however, are common and the Advisory Committee for Immunization Practices[91] found that half the patients who received the 14-valent pneumococcal vaccine developed side-effects, including erythema, mild pain at the injection site or transient fever[61] One other unusual complication is important; patients with idiopathic thrombocytopenic purpura may rarely find that their disease is exacerbated by immunization with pneumococcal vaccine[26].

The *Haemophilus* and meningococcal vaccinations also appear to be safe[29] and all three vaccines can safely be given together in a single dose without loss of immunogenicity[92]

Booster vaccinations. Repeat or 'booster' doses of pneumococcal vaccine are not recommended. After a second dose of pneumococcal vaccine side-effects and severe reactions are common[29,65,91], and it has also been shown that booster doses do not result in a substantial increase in serum IgG or IgM levels[65,73]. In addition, the risk of postsplenectomy infection is greatest in the years immediately after splenectomy and protective levels of antibody from one vaccination at the time of splenectomy should persist over this high-risk period[63,66,67,69]

A question that has arisen is whether patients previously immunized with a 14-valent pneumococcal vaccine should be reimmunized with the 23-valent vaccine? The American Academy of Pediatrics does not recommend this[93] because of the increased risk of adverse reaction. The Centers for Disease Control[94] also discourage this practice on the basis that the modest increase in coverage does not warrant the increased risk of possible adverse reaction. In contrast, Kafidi and Rotschafer[29] suggest that revaccination with the tetravalent meningococcal vaccine is indicated in children under 4 years of age.

Recommendations regarding the use of vaccines. In the light of the information presented above it seems reasonable to offer all splenectomized patients vaccination with pneumococcal, meningococcal and *H. influenzae* vaccines[8]. Patients undergoing elective splenectomy should ideally receive the vaccines before surgery[55], and patients with lymphoid tumours may gain some benefit if they receive these vaccines before therapy[78]. All three vaccinations can be given together[92] but they should not be administered at the same time as chemotherapy or other immunosuppressive treatment[78].

Patients having emergency splenectomy for trauma should be vaccinated as soon as possible after surgery[15,56].

Are other methods of prophylaxis worthwhile?

Other methods of preventing postsplenectomy infection include splenic salvage, autotransplantation and prophylactic antibiotic administration.

Splenic salvage

Although conservative management is the norm in many cases of childhood splenic trauma, it became unpopular earlier this century in adults as total splenectomy became safer. Recently, however, splenic salvage in adults has been reconsidered and many clinicians have used splenic conservation successfully. For instance, the Papua New Guinea Splenic Injury Study Group[34] describe a series of 205 adult patients with ruptured spleens from several hospitals. Initial non-operative management was attempted in 137 of these cases, and was successful in 80 per cent. King *et al.*[95] also describe a successful management plan for splenic trauma favouring non-operative treatment.

Conservation of part of the spleen has also been used effectively but estimates of the amount of spleen that needs to remain to protect a patient from infection vary. Ellison and Fabri[1] indicate that at least one-third of the splenic mass must be conserved to maintain splenic immune function. They also suggest that ligation of the splenic artery and salvage of the spleen via collateral blood supply, as used in animal models, reduces splenic blood flow to such a degree that the immunological protection offered by the spleen is lost. In contrast, Greco and Alvarez[96] have shown in rats that as much as 80 per cent of the spleen can be removed, and because the remnant undergoes hypertrophy, host protection against a subsequent pneumococcal challenge is preserved.

Whether small splenic remnants offer protection against infection is debated. Greco and Alvarez[96] suggest that partial splenectomy with conservation of even quite small portions of spleen attached to identifiable blood vessels yields significant protection from life-threatening sepsis. Similarly, Van Wyck *et al.*[97] have demonstrated an advantage of splenic remnant preservation over splenectomy in terms of antibody responsiveness Certainly conservation of the spleen is the ultimate prophylaxis for postsplenectomy infection and this approach should probably be used both in children and adults wherever possible[1].

Techniques of splenic salvage have been reviewed elsewhere[98]. For minor lacerations or capsular tears local pressure and the application of a topical haemostatic agent is usually successful[99]. More major injuries usually require some form of splenorrhaphy and this can be accomplished using simple suture, suture with Teflon® (du Pont) buttresses or the incorporation of an omental patch[98]. 'Cocooning' the spleen in a polyglycolic acid mesh has also been described[100].

Splenic autotransplantation

Four techniques of splenic autotransplantation have been used: into the abdominal wall, into an omental pouch, intraperitoneal injection and intrahepatic injection Ellison and Fabri[1] reviewed the literature on autotransplantation in 1983 and concluded that functioning splenic tissue could be produced in experimental animals by all of these techniques except intrahepatic injection. Although autotransplantation does provide a method for preserving some splenic function they concluded that it was inferior to partial splenectomy.

Many investigators have assessed the potential of autotransplantation in animal models. Moxon *et al.*[25] found that splenic autotransplantation reduced the incidence of *H. influenzae* meningitis in asplenic rats, while Likhite[101] also showed that subcutaneous splenic fragments gave some protection from pneumococcal infection in mice.

However other investigators have reservations. Scher *et al.*[35] indicate that while splenic autotransplantation does enable asplenic rats to develop a better antibody response to sheep erythrocytes it does not provide protection against pneumococcal infection. In accord with these observations Kiroff *et al.*[58] assessed the degree of ectopic splenic regrowth isotopically and after measuring the antibody response to pneumococcal vaccine and found that there was no difference in responsiveness between patients with splenosis and those without.

Summing up this problem, Greco and Alvarez[96] conclude that splenic autotransplantation 'remains an experimental procedure which cannot be reliably performed in humans if one's intent is to protect the recipient against infection.'

Antibiotic prophylaxis

Antibiotic prophylaxis has become the norm for selected postsplenectomy patients and is recommended by a number of clinicians. For instance, Franck and Neu[8] suggest using antibiotic prophylaxis in postsplenectomy patients with the following indications: low initial levels of antibody to pneumococci or a high risk of exposure to pneumococcal infection, and in those undergoing chemotherapy for malignancy or who are aged less than 5 years. Ammann and Diamond[102] recommend continuous antibiotic prophylaxis for children from the time of splenectomy up to the age of 5 years, while Ellison and Fabri[1] suggest that antibiotics are most important in the 2–3 years after splenectomy.

However, there are reports of prophylactic antibiotics failing to prevent infection[87,88], and some animal studies also cast doubt on their efficacy. For example, Scher *et al* [35] found that prophylactic penicillin does not increase the clearance of *Pneumococcus* from the blood of asplenic rats. Another problem with antibiotic prophylaxis is poor patient compliance[8].

Traditionally penicillin has been the prophylactic antibiotic of choice[1,7] However, the use of other antibiotics has been suggested and Singer[2] points out that half of the septic episodes in asplenic patients are due to organisms that are not sensitive to penicillin On this basis Frank and Neu[8] recommend amoxycillin as this is also effective against *H. influenzae.* On the other hand, Fillner (see Leonard *et al.*[7]) does not recommend amoxycillin for prophylaxis because it is more expensive than penicillin and because it has twice the incidence of allergic rashes. Kyong and Reines[103] conclude that the morbidity and expense of long-term ampicillin probably outweigh the benefits of its use

Prompt recognition and treatment of infection may be at least as useful as prophylactic antibiotics. Both Van Wyck[97] and Kyong and Reines[103] feel that a most useful way of preventing infection is to attend quickly to any febrile illness in an asplenic patient. This is further supported by the contention of Gullstrant *et al.*[104] that penicillin is more effective when given early after a pneumococcal challenge than when given late, and many clinicians give the patient a supply of ampicillin to use at the first sign of a respiratory illness or fever[19].

Browder *et al.*[105] used glucan, an immunostimulant, in splenectomized mice to increase phagocytic function, and observed a significant increase in survival following a pneumococcal challenge. There are, however, no human data available at present regarding glucan.

Conclusions

The primary aim of this review was to answer three questions.

What are the infectious consequences of splenectomy?

Postsplenectomy sepsis is rare following splenectomy for trauma and uncommon following splenectomy for other reasons. The patients most at risk are children and those splenectomized for lymphoreticular malignancy. The causative organism in about 50 per cent of cases is *S. pneumoniae* and more than 50 per cent of cases of OPSI occur within 2 years of splenectomy. However, *Meningococcus*, *Haemophilus* and other bacteria are also involved, and splenectomy may also increase the morbidity of some parasitic and viral infections.

How does removal of the spleen alter the immune system, and how effective are vaccines in preventing postsplenectomy infection?

Splenectomy reduces phagocytosis and clearance of micro-organisms, the elaboration of a specific immune response and the production of splenic opsonins. Vaccines are available against *Pneumococcus*, *Meningococcus* and *H. influenzae*. Studies of the antibody response to them have shown varying results but, overall, splenectomy appears to reduce antibody responsiveness. Other factors also known to reduce the response to vaccination include: age less than 3 years, haematological malignancy, immunosuppressive therapy and genetic profile. Surgery and/or anaesthesia do not appear to diminish responsiveness

In general, capsular polysaccharide vaccines appear to be effective in reducing the incidence of postsplenectomy infection although there are numerous reports of sepsis despite vaccination. Probably the optimal regimen is vaccination with pneumococcal, meningococcal and *H influenzae* vaccines as long as possible before operation for patients undergoing elective splenectomy, and for patients receiving immunosuppressive therapy the vaccine should be given between courses of treatment. Although responsiveness may be reduced in patients vaccinated after splenectomy for trauma, they should still receive vaccine as soon as possible after operation as they are likely to develop a protective response.

Serious side-effects following a single vaccination are rare but are common following a second or booster dose.

Are other methods of prophylaxis worthwhile?

In children splenic salvage is an accepted technique for preventing postsplenectomy infection. In adults conservative management of splenic trauma is emerging as a useful technique and should be considered whenever it can be accomplished safely.

Although splenic autotransplantation may have potential, there is insufficient evidence in humans for the technique to be widely promoted at present. Prophylactic penicillin should be used in addition to vaccination in asplenic patients at especially high risk of infection, notably children aged less than 5 years and immunosuppressed patients For other patients, in addition to vaccination, education regarding the prompt recognition and treatment of infectious illnesses is probably more appropriate

Gastrointestinal malignancy: rationale for adjuvant therapy using early postoperative intraperitoneal chemotherapy

W. J. Cunliffe and
P. H. Sugarbaker*

*Department of Surgery, University of Newcastle upon Tyne, UK and *Cancer Institute, Washington Hospital Center, Washington, USA*

Mr P. H. Sugarbaker, Cancer Institute, Washington Hospital Center, 110 Irving Street NW, Washington, DC 10020, USA

The treatment of gastrointestinal cancer and the prognosis of patients with this disease have changed very little over the past several decades. No screening tools have been developed which allow this disease to be surgically treated for cure at an early stage. None of the forms of adjuvant chemotherapy instituted in the months and years after surgical resection of cancer have been successful. We show that resection site recurrence and spread of disease on the peritoneal surfaces are the most common sites for surgical treatment failure. By changing the route of administration and the timing of chemotherapy, the efficacy of drugs now routinely employed in gastrointestinal cancer can be markedly improved. Our early studies suggest that there is a definite change in the natural history of these malignancies when intraperitoneal chemotherapy is administered immediately after surgery. The pharmacology and physiology of drug delivery in the immediate postoperative period are explored. Toxicity studies have been performed in a series of treatment protocols already in use. These protocols need to be subjected to randomized controlled trials in the near future.

Keywords: Gastrointestinal cancer, intraperitoneal chemotherapy

The three most common causes of malignancy of the digestive system, adenocarcinoma of the large bowel, stomach and pancreas, will affect approximately 200 000 patients in the USA this year[1]. While gastric malignancy has become less common, both colorectal and pancreatic malignancies are increasing in frequency[2], in Europe as well as in the USA[3]. Of newly diagnosed patients with such malignancy, far fewer than half will be alive and free of disease after 5 years[4–6]. The factors responsible for this poor outlook are discussed, together with the rationale for a new adjuvant treatment, namely early postoperative intraperitoneal chemotherapy. This treatment may modify the natural history of gastrointestinal cancer by reducing cancer spread at the resection site and on peritoneal surfaces. We suggest that this novel addition to the postoperative care of gastrointestinal cancer patients may have important although limited goals. The rationale for this approach comes from a study of the patterns of recurrence.

Patterns of recurrence

Surgical treatment failure with gastric cancer

Gastric cancer is often advanced at presentation[7], metastases may arise at an early stage of the disease[8] and the malignancy may be multifocal[9,10]. After curative surgery the 5-year survival rate in the USA is less than 20 per cent[11]. The probable reasons for this low survival rate are the high operative mortality rate of approximately 10 per cent and the high rate of local recurrence. Following surgical treatment, very few patients have recurrence confined to the liver or lung. Accurate autopsy series have consistently shown recurrent intra-abdominal disease in up to 75 per cent of patients[11–19]. Clearly, a major problem with gastric cancer is the frequent finding of local/regional recurrence.

The Japanese, who see many more patients with gastric cancer than surgeons in either Europe or the USA, have approached the problem with extensive data gathering. In conjunction with gastrointestinal endoscopists and pathologists, they have undertaken an aggressive surgical approach, with extensive anatomical documentation of extent of disease in each patient[20]. The result has been an increase in the operability rate, a reduction in the operative mortality rate and an improved survival[21], especially when compared with series from Europe or the USA[15,22]. Interestingly, the early Japanese results in the 1940s were similar to contemporary results in Europe or the USA. Improvement in their results began after the unified approach used by all concerned in the management of patients with gastric cancer. This approach has been adopted by a British group who were able to demonstrate, on a smaller scale, similar improved results[23]. Despite the greatly improved (approximately 70 per cent) 5-year survival rate achieved by the Japanese, they still accept the need for adjuvant therapy in the management of gastric cancer[24].

Surgical treatment failure with pancreatic cancer

Pancreatic cancer shares features that are characteristic of gastric neoplasms, such as advanced disease at presentation[5,25–28], multicentricity[29,30] and metastasis early in the disease[28,31]. Added to this is the fact that local recurrence is the most common site of disease recurrence with pancreatic cancer[32]. There is no doubt that some form of adjuvant therapy is indicated if any progress is to be made in the management of this condition.

The surgical approach to pancreatic cancer has been woefully inadequate. Despite surgery, over 95 per cent of patients will die of their disease within 5 years of diagnosis[33–36]. Surgical opinions have been divided over the most appropriate surgical therapy for this condition. Some authors have advocated palliative surgery only, as this therapy has been demonstrated to have fewer complications and a comparable median survival[37]. Other surgeons are undecided about how

0007-1323/89/101082–09$3 00 © 1989 Butterworth & Co (Publishers) Ltd

radical the surgery should be. Whipple's operation has been popular since its inception in 1935[38] and it has the advantage of removing the tumour without necessarily rendering the patient diabetic or prone to malabsorption. Total pancreatectomy avoids the need for a potentially troublesome anastomosis but may produce patients with a diabetic and metabolic state that is difficult to control[5,39]. Sindelar *et al.*[40] reviewed the literature on results of radical surgery for pancreatic cancer and found that the operative mortality for the Whipple procedure performed in 814 patients with this disease was 19·5 per cent compared with 22 per cent in 300 patients undergoing total pancreatectomy. Both groups had significant morbidity in at least half the patients. In the Whipple group, sepsis and fistula formation accounted for half of the complications, while sepsis and metabolic complications accounted for half of the complications in the total pancreatectomy group. Survival rates at 3 and 5 years were 13·1 and 8·1 per cent respectively in the Whipple group compared with 18·4 and 9·3 per cent in the total pancreatectomy group. It should be emphasized that these were not controlled comparative studies, but the comparison of published data from the literature.

Surgical treatment failure with colorectal cancer

This disease accounts for over half of the cases of gastrointestinal malignancy. Surgery alone is the current therapeutic option. As expected, there has been no major improvement in the overall 5-year survival rate in the last 40 years[41]. As with the other two gastrointestinal malignancies, the disease is often in an advanced state at presentation[42–44], with barely 20 per cent of patients having disease confined to the superficial layer of the bowel. Synchronous hepatic metastases may be present in approximately 15 per cent of patients[45–47].

Local/regional recurrence following surgery is a major problem with colorectal cancer, a fact that has been highlighted with respect to whether low anterior resections using a stapling device have higher recurrence rates than conventional techniques[48,49]. Local recurrence rates of up to 50 per cent have been documented in both rectal[50–52] and colonic cancer[52–58]. Clinical studies suggest that as many as one-third of all cases recur solely in the liver, although this has not been confirmed by the more accurate reoperative and autopsy series in which this figure is placed closer to 10 per cent[53,56,58]. In the series reported by Gunderson and colleagues, 74 per cent of all the patients who relapsed had either local–regional recurrence or peritoneal seedlings or both[58]. A review of collected reports in the literature in which 2565 cases of large bowel cancer were treated shows that of the 438 cases with recurrence, 42 per cent had a local component only, 27 per cent had a distant component only while the remaining patients had both local and distant recurrences[51,56,59–65].

Figure 1 is a schematic representation of recurrence typical of surgically treated gastrointestinal cancer. Patients will present with recurrent disease in the operative site, with peritoneal implants, with hepatic metastases, and with systemic metastases. An optimal adjuvant surgical therapy should be effective at all sites of recurrent disease, both local/regional and systemic. However, elimination of recurrence at a particular anatomical site may benefit a significant proportion of patients in terms of survival or quality of life.

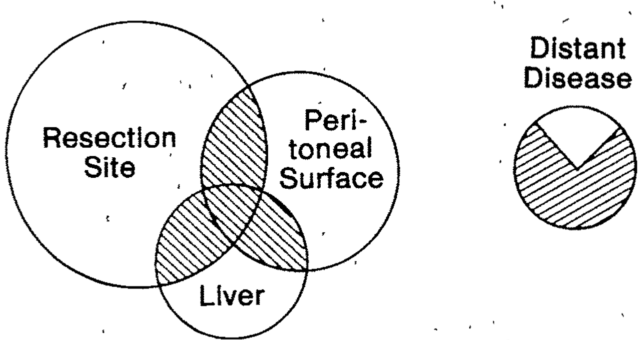

Figure 1 *Recurrence pattern in patients with gastrointestinal cancer. A combined recurrence (■) is more usual than isolated recurrence (□)*

Pathological indicators of patterns of recurrence of colorectal cancer

The routes of spread likely for an individual patient with gastrointestinal cancer are indicated by pathological studies of the primary tumour specimen. Penetration through the bowel wall is followed by circumferential growth of cancer. Intestinal obstruction is the eventual outcome. This results from tumour extension along transversely aligned lymphatic channels. Full thickness penetration of cancer through the bowel wall may result in peritoneal seeding, carcinomatous invasion of adjacent structures, or bowel perforation. Lymphatic spread does not usually occur until the bowel wall is penetrated by cancer[42,66] unless the tumour is poorly differentiated[43,67], in which case it can spread while still in the tip of an adenomatous polyp[68]. The more advanced the local disease, the more likely is both lymphatic[44,69] and haematogenous spread[70]. Haematogenous spread may occur directly through tumour emboli released into the portal vein or Batson's plexus. Haematogenous metastases may also occur via an indirect route, tumour cells passing from lymph nodes to the thoracic duct and to venous blood. Lymphatic spread is usually stepwise with involvement of the nodes closest to the lesion being followed by involvement of more distal nodes[71,72], but 'skip' metastases do occur[71,73], as does retrograde spread[74]. At the time of initial diagnosis, upwards of 20 per cent of patients may have evidence of haematogenous spread[75], and the histological finding of venous invasion in the primary tumour correlates well with the presence of haematogenous disease[76].

Despite curative gastrointestinal surgery, more than 5 per cent of patients will die from recurrent disease[77]. This recurrence follows 'removal' of the malignancy[78]. The possible mechanisms of surgical treatment failures have been outlined by Sugarbaker and colleagues[75]: (1) foci of neoplastic cells dislodged from the lateral margins of resection and lymphatic channels or present in venous blood may be disseminated as micrometastases on to peritoneal surfaces and into the resection site; (2) tumour cells may disseminate into veins before or at the time of surgery as a result of manipulation[79]; and (3) intraluminal tumour cells exfoliated at the site of bowel transection or on to mucosal margins may lead to anastomotic recurrence[80]. This last phenomenon may explain reports of anastomotic recurrence rates of up to 30 per cent[81–84], which can be reduced by using intraluminal irrigating solutions[85–87]. A recent review has covered this subject comprehensively[88]

A new hypothesis by which to understand the recurrence patterns of surgically treated gastrointestinal cancer is the fibrin entrapment hypothesis. This hypothesis separates the mechanisms by which recurrent cancer comes about into two groups 'tumour metastases' are viewed as a lymphatic or haematogenous dissemination that occurs before surgery but which is not recognized because of the small size of the malignant foci; 'tumour spread' is viewed as cancer dissemination that results from the inevitable trauma of the surgical removal of a gastrointestinal malignancy. Haematogenous spread can be prevented by gentle resection techniques and wide anatomical dissections. However, spread of tumour within the abdominal cavity into the resection site and on to peritoneal surfaces is unavoidable in patients with advanced tumours. Even though the tumour is removed with negative margins, tumour emboli from transected lymphatic channels, tumour emboli disrupted from narrow lateral margins of resection and tumour cells lost into the abdominal cavity will be trapped in the fibrin that occurs in the resection site and on abraded peritoneal surfaces. These tumour cells will be protected from host defences and systemic chemotherapy, causing a high incidence of intra-abdominal recurrence.

Systemic chemotherapy with or without radiation therapy

Gastric cancer

A review of the literature by MacDonald *et al.*[89] gives a comprehensive analysis of response rates for various single agent drugs used in trials of 14 or more patients. The response rate varies from zero with razoxane[90] to 36 per cent with doxorubicin[91]. Despite these response rates, the duration of response rarely exceeds a few months and complete responses are uncommon. Any response achieved with such therapy is often negated by the associated toxicity. This pessimistic experience contrasts with results from Japan where survival benefits have been reported with 5-fluorouracil (5-FU)[24]. Some concern should be expressed for some Japanese studies, as they appear to have dropped the control arm and make use of historical controls for comparison[19,92].

By combining various drugs, therapeutic synergism is anticipated Of the prospective studies using combinations, the Gastrointestinal Tumor Study Group study demonstrated a survival benefit[93]. Two other series[94,95] showed no survival benefit following adjuvant therapy. The British Stomach Cancer Group were unable to demonstrate survival benefits in patients treated with Mitomycin C and 5-FU after surgery compared with a surgery-only control group[96]. Other authors have used pharmacological manipulation of the chemotherapeutic drugs to improve response. For example, Machover *et al.* found that by adding folinic acid to 5-FU, response rates were improved[97] Other authors have used an oil base for the drugs in order to localize them to lymphatics and lymph nodes, again improving response rates[98]. Despite these manipulations, no significant survival benefit has been conferred when results are prospectively compared with those of surgery alone.

By combining radiotherapy and chemotherapy together, conflicting results have been achieved in gastric cancer patients. Some authors report responses[99,100] while others fail to demonstrate success with the method[101,102].

Pancreatic cancer

Untreated pancreatic cancer has a median survival of 3–4 months[36] and, as mentioned above, the majority of patients with pancreatic cancer have advanced disease. In many studies over 85 per cent of patients are unsuitable for curative resection. These patients are often nutritionally depleted and have a poor life expectancy. In the past, obtaining a histological diagnosis has often been difficult in a proportion of patients[103,104], although newer fine-needle cytology techniques improve the diagnostic rate[105]. As a result of these problems, studies investigating adjuvant chemotherapy for pancreatic cancer involve the use of drugs in patients where advanced disease is nearly always present.

As single agent therapy, 5-FU has been used in pancreas cancer. Davis *et al* reported the results from 129 patients treated with 5-FU by a variety of routes where the overall median survival was 4 months[106]. Survival was 6 months in the 25 patients receiving systemic 5-FU, while survival was 7 months in 21 patients receiving 5-FU in conjunction with radiotherapy. Oral 5-FU appears to be ineffective[107]. In 1979, the Gastrointestinal Tumor Study Group studied patients after surgery and compared patients treated with 5-FU with moderate dose radiotherapy (4000 cGy) or 5-FU with high dose radiotherapy (6000 cGy) with patients treated with 6000 cGy alone. Those patients treated with 5-FU and any type of radiotherapy survived longer than those treated with radiotherapy only (35 *versus* 18 weeks), whereas those treated with high dose radiotherapy and 5-FU survived longer than those treated with low dose radiotherapy and 5-FU (39 *versus* 31 weeks). However, this survival difference between the high and low dose radiotherapy groups was not maintained after 1 year[108]. An update of this study has shown that the median survival in the adjuvant treated group was 20 months compared with 11 months in the surgery-only group[109]. Projected 2-year survival was 42 per cent in the adjuvant group compared with 15 per cent in the surgery-only group.

Several combinations of drugs have been studied. The response rates vary from 7 to 48 per cent without the median survival being affected. An interesting development in chemotherapy for pancreatic cancer is the discovery of oestrogen receptors in pancreatic tumour tissue, suggesting a possible role for agents such as tamoxifen[110]. Initial reports in the Scandinavian literature have been encouraging[111] but the results of definitive studies are awaited.

In pancreatic cancer, the combination of these methods of treatment, with or without surgery, has resulted in some reports of improved survival[26,112–114]. However, it is clear that adjuvant chemotherapy does not necessarily confer a major advantage and there is a long way to go before significant progress is achieved.

Colorectal cancer

With colorectal cancer a large number of studies have been generated using adjuvant chemotherapy. Few of the difficulties outlined above with respect to pancreatic cancer are applicable to colorectal cancer: histological diagnosis is usually easier to obtain, the majority of patients will undergo resection, and at least 70 per cent of patients will undergo curative resection[115,116].

The use of single agents in adjuvant therapy has been investigated, with one early report of the use of intraperitoneal Thiotepa showing no advantage[117]. The Veterans Administration Group studied the use of 5-FU in patients with poor prognosis and in palliative surgery-only patients and were able to demonstrate a trend towards prolonged survival in the treatment groups: 33 *versus* 26 per cent in surgery-only controls at 7 years in poor prognosis patients, 38 *versus* 26 per cent for surgery-only controls at 18 months in palliative surgery-only patients[94]. These differences did not achieve statistical significance. Grage *et al* [118] confirmed this trend in a further study of 210 patients undergoing curative surgery for whom overall survival rates were 56 *versus* 50 per cent for controls at 5 years: but it was noted that in Dukes' C patients, prolongation of the disease-free interval just achieved statistical significance ($P = 0{\cdot}04$). A similar result was found in rectal cancer patients. This small benefit attributable to 5-FU has been reported consistently[119] Other studies have reported benefit with other single agents using historical controls, but prospective randomized studies invariably fail to demonstrate survival benefit using these drugs.

Several studies have examined the use of combination chemotherapy as an adjuvant to surgery. Although survival benefits are only infrequently demonstrated, the trend towards improved survival in patients with more advanced disease was seen. The NSABP study[120] showed that for colonic cancer patients treated with 5-FU, semustine and vincristine, the survival benefit achieved ($P = 0{\cdot}05$) was independent of Dukes' classification. As far as rectal cancer is concerned, the NSABP trial[121] reported increased disease-free survival in patients treated with chemotherapy following curative resection when compared with controls treated by surgery alone. In this study, patients with rectal cancer treated with surgery plus postoperative radiation therapy showed no survival advantage.

In colorectal cancer, some authors have reported benefit by combining the modalities, compared with surgery alone[122], while others have found that any benefit derived was confined to patients with advanced disease[91].

Patients with metastatic disease are usually excluded from these studies, but some authors have attempted to prevent hepatic secondaries with chemotherapy. Taylor and associates reported encouraging results with this method where 5-FU was perfused via a portal vein catheter[123]. Updates of this work continue to be favourable[124] and a recent presentation by Kemeny and associates[125] notes the advantage of giving 5-FUdr via the hepatic artery when compared with intravenous use in patients with metastatic hepatic disease. However, intra-arterial 5-FUdr may give rise to sclerosing cholangitis[126].

As with the other gastrointestinal malignancies, encouraging response rates with gross disease have not been translated into improved survival for the group as a whole. Possibly, the proportion of cancer cells killed with systemic chemotherapy is too small to translate into significant differences in survival. Modest prolongations of disease-free survival reflect some reduction in tumour burden, but these weak effects are incapable of translating into overall survival benefits. It seems reasonable to propose that when tumour bulk is minimal, such as following resection of Dukes' A or B tumours, adjuvant therapy would be at its most effective. Unfortunately, these beneficial effects are statistically not appreciated because a major proportion of such patients survive with surgery alone. The successes are obscured by the large number of patients not needing adjuvant therapy. The much poorer survival of patients with 'advanced' primary tumour may allow weak effects to be detected in well conducted clinical trials.

In summary, we suggest that the population of patients who might benefit most from weak effects are those in whom the effects are most difficult to detect in a clinical trial. Studies have consistently shown that if systemic adjuvant therapy is effective at all it is in those patients with the more advanced primary disease rather than those with lymph node negative primary tumour.

Early postoperative intraperitoneal chemotherapy: a new adjuvant treatment

Intraperitoneal chemotherapy has been used, with limited success, for at least 30 years[125,127,128]. The pharmacodynamics of intraperitoneal chemotherapy have been documented by Dedrick *et al.*[129]. The most fundamental observation in their pharmacokinetic modelling studies was that the peritoneal clearance of a drug was inversely proportional to the square root of its molecular weight. Thus, large molecules (like many cancer chemotherapy agents) take longer to clear from the peritoneal cavity than smaller ones. This rule is true as long as the compound is not highly lipid-soluble, in which case permeability is increased. These authors established that: (1) large volumes of the drug-containing solution should be used to ensure exposure of the entire peritoneal surface; (2) to prevent systemic toxicity, the ratio of total body clearance to peritoneal clearance should be high; (3) because of limited penetration into tissue, the tumour to be treated should have small bulk; (4) co-administration of drugs which impair the hepatic or renal (systemic) clearance of the drug should be avoided.

Unwillingness to initiate protocol studies with intraperitoneal chemotherapy at different stages in the natural history of gastrointestinal cancer has occurred for several reasons. First, the delivery of drugs by the schedules usually employed with systemic agents results in multiple delivery-related complications. Tenckhoff catheters used over prolonged periods routinely fail to give uniform intra-abdominal drug delivery. There is a natural fibrotic reaction to the plastic catheter. Also, many of the agents have a sclerotic effect on peritoneum. These two factors, together with the adhesive effects of surgery, cause drug delivery to be completely inadequate. Furthermore, most oncologists have been unwilling to accept that resection site and peritoneal surface recurrences are major factors in the natural history of these diseases. This is, in large part, due to the lack of radiological techniques to demonstrate recurrent tumour at these sites. This must be contrasted with the large number of radiological studies that precisely identify cancer within liver and lungs. The only accurate studies establishing recurrence patterns of gastrointestinal cancer are those based on autopsy series or reoperative experiences. If local and regional recurrences are accepted as important surgical treatment failures, the best adjuvant to prevent these recurrences would be early postoperative intraperitoneal chemotherapy. The rationale for the use of intraperitoneal chemotherapy as an adjuvant in the immediate postoperative period is given in *Table 1*.

Table 1 *Rationale for the use of immediate postoperative intraperitoneal chemotherapy for gastrointestinal cancer*

1. The resection site and peritoneal surfaces are at high risk for recurrence. These surfaces are fully exposed to intraperitoneal chemotherapy in the immediate postoperative period
2. Pharmacological studies show a favourable therapeutic ratio for ablation of residual tumour microemboli on peritoneal surfaces
3. In the postoperative period, the surgical techniques for drug delivery are simple. They reliably give uniform drug delivery to peritoneal surfaces
4. For most drugs, intraperitoneal delivery does not compromise systemic exposure. Regional chemotherapy administration causes increased local effects without decreasing possible systemic disease control
5. The cost of therapy is minimal The patient is already in the hospital recovering from surgery. No expensive postoperative visits to receive other forms of adjuvant chemotherapy are required
6. There is minimal increased postoperative morbidity and no increased mortality with immediate postoperative intraperitoneal chemotherapy

The technique of immediate postoperative chemotherapy is quite simple. It involves inserting a Tenckhoff catheter at the completion of surgery to remove a primary gastrointestinal cancer. In the immediate postoperative period the catheter must be flushed with isotonic peritoneal dialysate fluid at a moderate rate. We use 1-litre abdominal lavage every hour for 4 h and then every 4 h until intraperitoneal chemotherapy begins. This fluid exchange ensures patency of the catheter by preventing fibrin and debris from collecting in it. A further advantage from this lavage of the peritoneal space may be the removal of growth factors. Inflammatory cells and healing tissue produce a variety of growth factors which may provide an environment in which residual carcinoma cells proliferate[130]. Colonic tumour cells have certainly been found to have enhanced growth rates in the presence of the typical inflammatory response preceding wound repair (unpublished results cited in Reference 131). We have shown that the intraperitoneal polymorphonuclear leucocytosis from inflammation in response to surgery subsides within 4 days[132].

On the first postoperative day, the intraperitoneal chemotherapy begins. One litre of dialysate containing chemotherapy is run through the Tenckhoff catheter in approximately 15 min. The catheter is then clamped until the next dose is due, at which point remaining fluid is allowed to run out. At all times, a strict aseptic technique is used when dealing with the catheter tip and with the skin exit site of the Tenckhoff catheter.

We have chosen to study the intraperitoneal pharmacology of a relatively small number of drugs (*Figure 2*). They all have certain characteristics that make them suitable for study, namely: (1) well documented use in systemic therapy; (2) a response rate greater than 20 per cent when used in gastrointestinal malignancy, (3) using Dedrick's criteria for intraperitoneal drug selection, all have potentially good characteristics and should provide a significant pharmacological advantage. Some of the drugs that we use, such as doxorubicin, may be questioned on grounds of chemical peritonitis[133] or toxicity. However, in animal studies, intraperitoneal doxorubicin has been shown to be very effective[133] and has the potential for intralymphatic activity when used with lipid microspheres[134].

The ideal regional chemotherapy regimen will not only treat residual intraperitoneal tumour, but will retain the possible systemic effects of these drugs. With intraperitoneal 5-FU administration, the plasma level of 5-FU 30 min after a 20 mg/kg dose approaches 30 per cent of that from a bolus dose of intravenous 5-FU of 15 mg/kg[135–137] and is 20 times that from a continuous infusion of 30 mg/kg per 24 h[138,139].

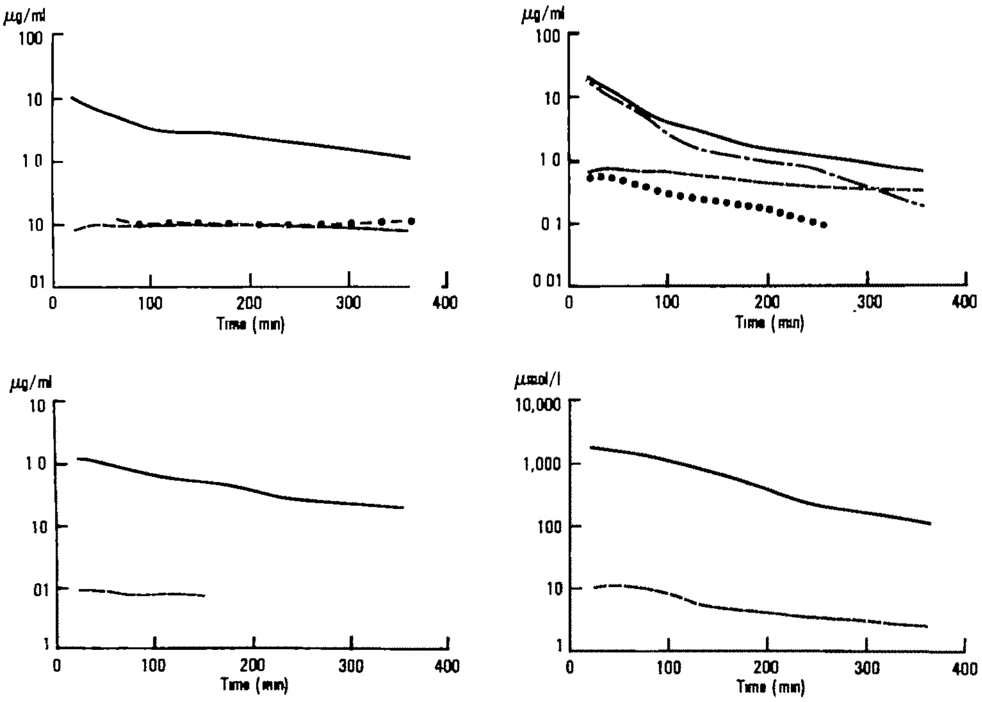

Figure 2 *Concentration* versus *time curves for four drugs effective in the treatment of gastrointestinal cancer and administered by the intraperitoneal route in the early postoperative period.* **a** *Concentrations in peritoneal fluid (——), portal plasma (●) and peripheral plasma (– – –) after intraperitoneal Mitomycin C (12 mg/m² in 2 litres).* **b** *Concentrations in peritoneal fluid (——), filtered peritoneal fluid (— - —), peripheral plasma (– – –) and filtered peripheral plasma (●) after intraperitoneal cisplatin (40 mg/m² in 2 litres).* **c** *Concentrations in peritoneal fluid (——) and peripheral plasma (– – –) after intraperitoneal doxorubicin (2 5 mg in 2 litres).* **d** *Concentrations in peritoneal fluid (——) and peripheral plasma (– – –) after intraperitoneal 5-fluorouracil (20 mg/kg in 2 litres)*

The area under the concentration *versus* time curve for the plasma level achieved from an intraperitoneal dose is considerably greater than that from an intravenous bolus but is associated with a lower likelihood of systemic complications.

Some agents have already been studied in detail in delayed postoperative intraperitoneal chemotherapy, notably 5-FU[140–1145], doxorubicin[146,133] and cisplatin[147]. A direct comparison of intraperitoneal *versus* intravenous 5-FU has been undertaken[148] and although no difference in survival was apparent, the natural history of colonic cancer was significantly altered by the intraperitoneal 5-FU, resulting in diminished peritoneal tumour implantation. The fact that no survival benefit was demonstrated following intraperitoneal chemotherapy may have been due to delay in chemotherapy administration and to the fact that patients with advanced cancer often have a combination of local–regional and distant disease.

Intraperitoneal penetration of tumour deposits by drugs is known to be limited; agents such as doxorubicin probably penetrate only a few cell layers[149,150] whereas cisplatin may penetrate as far as 2–3 mm[151,152]. Clearly a major rate-limiting factor in intraperitoneal chemotherapy will be this penetration and this may explain the varied success of studies so far using other agents such as methotrexate[153], melphalan[154], Mitomycin C[155] and 5-FU[148].

Systemic chemotherapy has been compared with intraperitoneal chemotherapy with respect to frequency of toxic reactions[148]. No difference in the incidence of toxicity was noted between the two groups but the severity of toxic reactions in the intraperitoneal group was markedly reduced. Toxicity from intraperitoneal therapy appears to be limited to local complications such as chemical peritonitis[146], escape of drug into subcutaneous tissues[156], and abdominal pain[141]. The reason for the reduced systemic toxicity is simply that if the appropriate drug is chosen, then the extraperitoneal systems will not be exposed to as high a level of drug as the intraperitoneal cavity. Thus, although local toxicity problems may occur as frequently with intraperitoneal 5-FU as systemic toxicity with intravenous 5-FU, the nature of the complications is less serious for the patient. This has been the case with early postoperative intraperitoneal chemotherapy in that there has been minimal myelosuppression.

Widespread intra-abdominal disease is not suitable for treatment with intraperitoneal chemotherapy. The exception to this rule is those patients with pseudomyxoma peritonei where the tumour cells are bathed in a large quantity of mucus. This makes an ideal medium for penetration by intraperitoneal chemotherapy and good results have been reported[157].

Pharmacokinetic studies are an essential part of early intraperitoneal chemotherapy studies. A typical study is demonstrated in *Figure 2*, which shows the concentration *versus* time curve for four drugs effective in the treatment of gastrointestinal cancer. The pharmacological advantages of intraperitoneal 5-FU chemotherapy used in the early postoperative period compare well with those reported by other authors where patients were not treated immediately after operation and therefore had a more normal peritoneal cavity[143]. Our intraperitoneal concentration *versus* time curve would appear to be slightly different: the possible reasons for this may be related to the presence of fibrin in the peritoneal cavity. In the immediate postoperative period there is a considerable sequestration of fibrin on the traumatized tissues. This fibrin may act as a mixing barrier which might alter the diffusion of small molecules.

The management of patients with gastrointestinal malignancy should be based on the knowledge that up to 40–50 per cent of patients will have intra-abdominal recurrence. New treatment plans should make use of the pharmacological advantage of intraperitoneal chemotherapy demonstrated so far. It is to be hoped that the alteration in natural history that has been achieved can be translated into improved survival. It will clearly be some time before the appropriate doses and regimens are determined, following which phase III studies would be required. The preliminary results of the therapy would appear to give reason for cautious optimism that the survival benefit for patients with gastrointestinal malignancy can be increased. We would suggest that early postoperative intraperitoneal chemotherapy could become part of a treatment strategy, which also makes use of preoperative radiotherapy and surgery as sequential multimodality adjuvant regional therapies to treat patients with gastrointestinal malignancy[143].

Survival differences in patients treated with early postoperative intraperitoneal chemotherapy cannot be seen to-date. The initial dose escalation studies were performed in 1987, so that limited follow-up is available. To-date, no randomized controlled studies have been initiated. However, clinical follow-up strongly suggests that the natural history of gastrointestinal cancer is modified by early postoperative intraperitoneal chemotherapy. Resection site recurrence and spread on peritoneal surfaces has not been seen in the follow-up of treated patients. Systemic disease recurrence has been documented with the expected recurrence rates.

Paper accepted 2 May 1989

Examinations leading to the FRCS diploma

At the Annual Meeting of the Association of Surgeons of Great Britain and Ireland, with the President, Professor Sir Patrick Forrest in the Chair, it was unanimously agreed that the following statement represented the views of the Association:

The Association of Surgeons of Great Britain and Ireland accepts that the FRCS diploma is no longer a qualification which signifies sufficiency of knowledge in all areas of surgery. This position has arisen by the step-to-step development of a series of major specialties (e.g. orthopaedics, urology, etc.) within what used to be general surgery, each of which requires an extensive period of training following acquisition of the FRCS diploma as we now know it. These specialties do not accept that the present Fellowship is appropriate to their needs. They recognize the need for, and indeed demand, a stringent assessment of competence during the training period.

General surgery, as is now defined, i.e. gastrointestinal, breast and endocrine, vascular and transplant surgery, trauma, etc. is no different from any other surgical specialty, demanding similar periods of specialty training and assessment of knowledge. Logically this assessment can only be held during that period of specialist training, i.e. after the time of the present FRCS. The Association believes that it is at this stage that the FRCS diploma should be awarded, as we understand is also the view of other specialty associations.

Were this to be agreed, a period of basic training before training in a specialty (including general surgery) is necessary during which time the young surgeon is exposed to surgery in all its various forms. This allows him or her to experience different surgical specialties and to decide about the direction in which his or her career should go. At this stage the young surgeon must be examined in knowledge which is common to all forms of surgical practice. This test of basic core knowledge should be in depth in selected areas. Detailed knowledge of much of general surgery is acquired during the higher surgical training period and cannot be assessed during this basic training period.

The Association cannot see that such an assessment of this basic core knowledge should require two separate examinations. It should be possible within the structure of a single examination, which would form Part I of the FRCS (new type). It would clearly be important that the young surgeon received some formal affiliation to a College after passing this examination; but it is inappropriate that this should be the Fellowship.

Those currently enrolled in higher training programmes in general surgery require special consideration and should not be eligible to take any additional examinations.

The Association therefore wishes to state as its views that:

1. General surgery (i.e. surgery of the gastrointestinal tract, breast and endocrine, vascular and transplant surgery, trauma, etc.) must now take its place alongside orthopaedics, urology, etc. as a specialty in its own right which merits similar periods of training and methods of assessment

2. Two examinations only should be necessary to assess the competence of a general surgeon to practise: the first an assessment of core knowledge including basic sciences common to all surgical specialties including general surgery; the other a test of knowledge in general surgery as a specialty

3. Although some form of college affiliation will be necessary after satisfactory completion of the first assessment, the FRCS diploma proper should be awarded only after both parts have been satisfactorily completed

4. Those enrolled in higher training programmes in general surgery at the time of these changes should not be eligible to sit a further examination.

Endoscopic palliation of malignant biliary obstruction in a child

K. I. Bickerstaff, B. J. Britton and M. H. Gough

Department of Surgery, Level 2, John Radcliffe Hospital, Headington, Oxford OX3 9DU, UK
Correspondence to: Mr K. I. Bickerstaff

The palliation of malignant biliary obstruction by the endoscopic insertion of an endoprosthesis is rapidly gaining acceptance as a safer alternative to surgical bypass[1]. Endoscopic palliation has been restricted almost entirely to elderly, unfit patients, but we report here the successful use of the technique in a 2-year-old boy.

Case report

A 2-year-old boy presented with anaemia, hypertension and a rapidly enlarging abdominal mass. Laparotomy revealed a large tumour apparently arising from the right kidney and extending retroperitoneally across the midline. Resection was not possible because of extensive accessory vasculature and the envelopment of the aorta and vena cava by tumour. Although biopsies were not diagnostic the tumour was thought to be a nephroblastoma and the appropriate chemotherapy was begun. Four days after the laparotomy the child suffered a large haemorrhage into the tumour. Although the bleeding was eventually controlled by embolization of the renal artery the child remained gravely ill. Ten days later his condition had improved sufficiently to allow a second laparotomy. The tumour was found to be much smaller and considerably less vascular and a right nephrectomy was performed. Although the majority of the mass was resected, residual tumour remained around the duodenum, common bile duct and inferior vena cava. Postoperative recovery was soon complicated by progressive jaundice and the child's condition deteriorated rapidly. The serum bilirubin and alkaline phosphatase levels rose to 282 μmol/l and 1362 units/l respectively, and ultrasonography revealed markedly dilated intrahepatic and extrahepatic bile ducts. To avoid a third laparotomy it was decided to try to relieve the biliary obstruction by the endoscopic insertion of an endoprosthesis.

Duodenoscopy was performed under general anaesthesia using an Olympus JF-1T 10® duodenoscope (Olympus Keymed, Southend, UK). The pancreatogram was normal but retrograde cholangiography showed extrinsic compression of the distal bile duct with proximal dilatation (*Figure 1a*). Under radiological control a Teflon® (E.I. du Pont de Nemours and Company, UK) coated guide-wire was negotiated across the stricture and a 5-cm, 8 Fr Leung-Cotton-type endoprosthesis was then railroaded into position (*Figure 1b* and *c*). A sphincterotomy was not performed and the procedure was uncomplicated except for a transient, asymptomatic rise in the serum amylase over the following 18 h. The jaundice resolved steadily and the child's general condition began to improve. Histology of the tumour removed at the second laparotomy showed it to be an undifferentiated intrarenal neuroblastoma rather than a nephroblastoma and the chemotherapy was changed to a more appropriate regimen. The boy left hospital 1 month after the insertion of the prosthesis and at discharge was free of jaundice and had virtually normal liver function tests. He has now been followed up for 4 months and has completed six courses of chemotherapy. He has made good progress, the jaundice has not recurred and the residual tumour has shown some signs of regression.

Discussion

The value of diagnostic endoscopic retrograde cholangiopancreatography (ERCP) in paediatric practice is now well established[2], but the therapeutic procedures derived from ERCP have been used infrequently. We believe that this is the first report of an endoscopically inserted endoprosthesis used to relieve biliary obstruction in a child.

We used virtually the same technique and equipment as employed in adults, the only differences being the use of general anaesthesia rather than intravenous sedation and the insertion of a shorter, smaller calibre prosthesis. The procedure was entirely straightforward; not only did it result in the complete resolution of the jaundice, but it avoided the necessity of a third laparotomy in a seriously ill child and led to no additional morbidity. Biliary obstruction due to an incurable malignancy

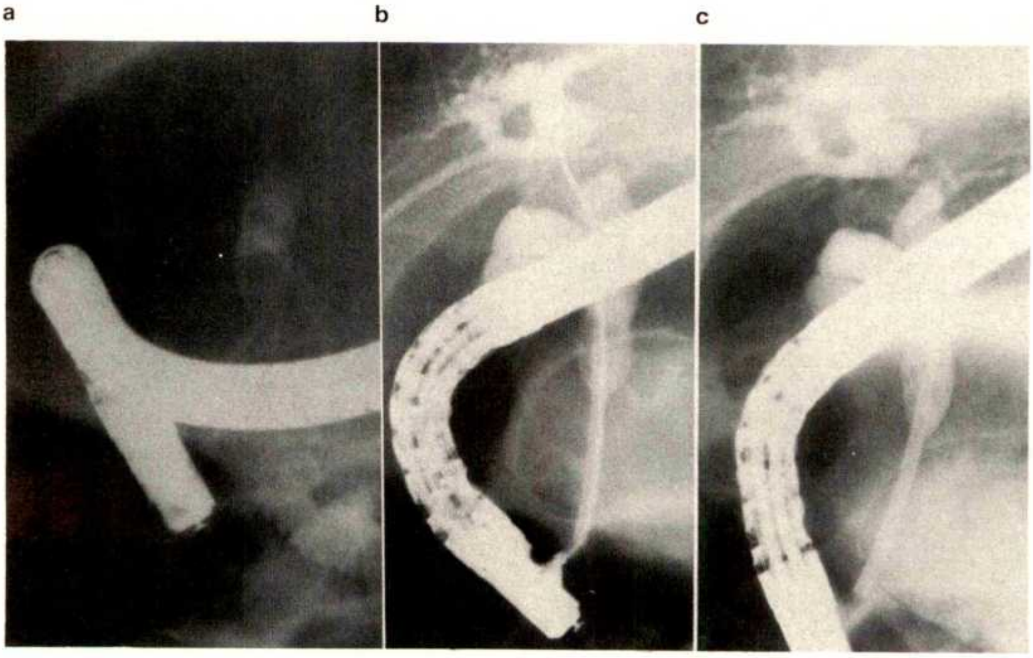

Figure 1 *Insertion of the endoprosthesis:* **a** *the extrinsic compression of the bile duct with proximal dilatation;* **b** *and* **c** *the endoprosthesis being railroaded into position. The filling defects in the bile duct are air bubbles not stones*

is fortunately rare in children. However, when such an event occurs we suggest that the use of endoscopic palliation should be considered, and experienced endoscopists should not be reluctant to attempt the procedure in children.

Intrarenal neuroblastoma is a rare tumour and our case illustrates how it can be readily mistaken for the commoner Wilms' tumour. Rosenfield and colleagues have described six similar cases which were clinically and radiologically indistinguishable from Wilms' tumour[3]. It is unclear whether these tumours arise from intrarenal rests of neural crest tissue or originate in the adrenals and invade into the kidney. They are usually undifferentiated, aggressive tumours and have a poor prognosis.

New way to take pinch grafts

L. Hands and J. Collin

Nuffield Department of Surgery, University of Oxford,
John Radcliffe Hospital, Headington, Oxford OX3 9DU, UK
Correspondence to: Miss L. Hands

Pinch grafts are traditionally harvested from an anaesthetized square or rectangle of skin, leaving intact skin between excised areas. This practice is time consuming and leaves a large raw area which is often more uncomfortable for the patient than the wound that is being treated.

We have modified the technique by excising a 3-mm wide strip of skin (*Figure 1*) which is then cut into 3-mm lengths. The strip of skin is incised obliquely so that the edges of the strip are partial thickness to mimic this valuable characteristic of pinch skin grafts. It is essential that the skin is carefully cleaned of any subcutaneous tissue before the strip is subdivided into its short lengths. The donor site is closed with a subcutaneous Prolene® (Ethicon Ltd., Edinburgh, UK) suture to give a linear scar which, if the site has been well chosen, is unobtrusive and almost painless.

Nucleolar organizer regions and cell ploidy in the interpretation of parathyroid histology

B.J. Jenkins, J.E. Martin, M.W. Lowdell and A.W. Goode, *The London Hospital, London E1, UK*

The accurate histological differentiation between adenomas, hyperplastic and normal parathyroid glands is vital to the correct operative strategy in patients with primary hyperparathyroidism. However, this distinction may be unclear by conventional histological techniques.

Recent reports suggest that the number of nucleolar organizer regions (NOR) per nucleus may facilitate the distinction between malignant or benign or normal cells. This study comprised 27 paraffin-fixed sections of parathyroid tissue from patients who had undergone surgery for primary hyperparathyroidism. Eleven glands were considered on conventional histological criteria to be hyperplastic, ten adenomatous and six normal. The number of NOR per nucleus was counted in 50 cells per slide. DNA flow cytometry was also performed on 20 sections of parathyroid tissue using a Becton–Dickinson FAC scan (Becton-Dickenson UK Ltd., Oxford, UK) with on-line computer; 10 000 cells per section were counted and the results analysed with standard DNA cell-cycle software using a sum of broadened rectangles model. Seven glands were hyperplastic, six adenomatous, four normal and three were carcinomas.

The mean NOR count per nucleus in normal parathyroids was 3·1 (range 2·9–3·4) in contrast to adenomas (mean 4·1; range 3·7–4·4) and hyperplastic glands (mean 4·3; range 3·7–4·7). Normal glands had a lower NOR count than abnormal glands ($P<0\cdot05$, Mann–Whitney U test). DNA analysis showed 16 of 20 (80 per cent) parathyroid sections to be diploid; four glands (two adenomas, one hyperplastic and one carcinoma) were aneuploid.

We have subsequently performed NOR staining successfully on frozen sections of parathyroid tissue. The technique may have some potential value as an indicator at the time of surgery as to whether a parathyroid gland is normal or abnormal; in contrast, cell ploidy is unlikely to be useful.

Flow cytometric analysis of phaeochromocytomas and paragangliomas: prognostic significance of ploidy

O. Nativ, C.S. Grant, G.M. Farrow, T.M. Therneau, S.G. Sheps, J.A. van Heerden and M.M. Lieber, *Mayo Clinic, Rochester, Minnesota 55905, USA*

It is generally conceded that to distinguish histologically benign from malignant phaeochromocytomas (Ph) in the absence of demonstrated local invasion or metastatic disease is not reliable. Even though only approximately 10 per cent of Ph ultimately prove to be malignant, this figure rises to nearly 40 per cent in paragangliomas (Pa). An expedient method which would provide prognostic information would be valuable. We previously reported that patients whose Ph were DNA normal (diploid) by flow cytometric analysis followed a benign clinical course[1]. The purposes of this study were to enlarge the previous study group of Ph and to analyse Pa by the same technique.

The prognostic evaluation, operative procedure, histological assessment and follow-up clinical course were investigated. Tissue preparation of dissociated, stained nuclei and flow cytometric histograms were as described previously. Satisfactory histograms were achieved on paraffin-embedded tumours from 180 patients. The average age of patients was 44 years (range 3–82) with 100 men and 80 women.

Relating DNA histograms to clinical outcome, with a mean follow-up of 10·1 years (range 1 month–36·5 years), DNA histograms were classified as shown in the *Table*.

All patients with DNA normal Ph or Pa (mean follow-up >11 years) had no evidence of malignancy by either histology or subsequent clinical course. By contrast, tumours with either tetraploid/polyploid (T/P) or aneuploid (A) histograms exhibited malignant characteristics significantly more frequently than DNA normal tumours ($P<0\cdot05$).

	Evidence of malignancy*		
DNA histogram pattern	(−)	(+)	Total
Ph			
Nl	62 (100)	0 (0)	62
T/P	40 (74)	14 (26)	54
A	40 (75)	13 (25)	53
Total	142 (84)	27 (16)	169
Pa			
Nl	3 (100)	0 (0)	3
T/P	3 (75)	1 (25)	4
A	2 (33)	4 (67)	6
Total	8 (62)	5 (38)	13

*Tumour invasion, local recurrence, or distant metastases; Nl, normal (diploid); T/P, tetraploid/polyploid; A, aneuploid. Values in parentheses are percentages

These results confirm the value of flow cytometric DNA ploidy analysis in yielding useful prognostic information for patients with Ph and Pa.

Influence of adenoma weight on the secretion of intact parathyroid hormone (PTH) in primary hyperparathyroidism

J.G. Williams, M.H. Wheeler, J.P. Aston*, R.C. Brown* and J.S. Woodhead*, *Departments of Surgery and *Medical Biochemistry, University Hospital of Wales, Heath Park, Cardiff, UK*

A sensitive and specific immunochemiluminometric assay for intact (1–84) parathyroid hormone (PTH) has provided enhanced diagnostic accuracy in hyperparathyroidism and facilitated investigation of the mechanisms of PTH secretion[1].

The present study examines the relationship between preoperative serum PTH concentration and parathyroid adenoma weight in 44 patients undergoing surgery for primary hyperparathyroidism due to single gland disease. Mean(s.d.) preoperative corrected serum calcium was 2·86(0·23) mmol/l. Maximum serum PTH concentration ranged from 8·5 to 177·4 pmol/l (median 23·2 pmol/l). Adenoma weight ranged from 140 to 15 230 mg (median 760 mg). There was no significant correlation between preoperative serum calcium and either PTH concentration or adenoma weight ($r=0\cdot465$, $r=0\cdot381$ respectively). There was, however, a highly significant correlation between PTH concentration and adenoma weight ($r=0\cdot850$, $P<0\cdot0005$). Patients with adenomata heavier than 750 mg had a lower circulating PTH level per mg adenoma than those with smaller glands ($P<0\cdot00001$, Mann–Whitney U test).

PTH secretion by dispersed parathyroid adenoma cells was examined *in vitro*. The mean(s.d.) PTH secretion rate (pmol/10^5 cells/h) in low calcium medium (0·5 mM Ca^{2+}) from eight adenomata weighing <1000 mg was 91·2(143), there being no correlation between secretion rate and original gland weight. Two large adenomata weighing 2700 and 4200 mg secreted only 2 and 42 pmol/10^5 cells/h respectively.

We conclude that although *in vivo* there is a strong correlation between intact PTH secretion and adenoma weight, larger glands appear to secrete less PTH per unit weight and per unit cell *in vitro* under conditions of maximum stimulation.

Hyperparathyroidism and pancreatitis

J.F. Buckley, C.R. Chapple and E.J.G. Milroy, *Department of Urology, Middlesex Hospital, Mortimer Street, London W1, UK*

The relationship between hyperparathyroidism (HPT) and pancreatitis is controversial, but HPT-induced hypercalcaemia is considered to be a rare cause of pancreatitis. A review of 650 consecutive parathyroidectomies revealed 15 cases of pancreatitis associated with HPT, an incidence of 2·3 per cent. In 14 cases acute pancreatitis was the presenting factor and in one case pancreatitis developed as a result of post-parathyroidectomy hypocalcaemia. All patients were hypercalcaemic, mean 3·0 mmol/l (2·6–4·2). The patient with hypocalcaemic pancreatitis had a calcium level of 1·79 mmol/l. Two cases had recurrent acute pancreatitis and one patient developed chronic pancreatitis. Four patients had pancreatic pseudocysts, two of which were drained surgically. One patient had a total pancreatectomy for chronic pancreatitis. There were no new episodes of pancreatitis after parathyroidectomy.

The parathyroid histology was adenoma in ten cases and nodular hyperplasia in five cases All patients became normocalcaemic post-parathyroidectomy except for one who remained hypercalcaemic.

In conclusion, pancreatitis is a complication of HPT. In patients ill with pancreatitis an early parathyroidectomy may benefit in recovery from pancreatitis.

Results of reoperation for persistent or recurrent secondary hyperparathyroidism

J.F. Henry, A. Denizot, J. Audiffret and G. France, *Department of Endocrine Surgery, University Hospital of the Timone, Marseilles, France*

Two hundred and fifty-eight patients were operated on for secondary hyperparathyroidism (HPT II) between 1971 and 1988 and 33 patients had 37 operations for persistent or recurrent HPT. There was no significant morbidity and no mortality.

Eighteen patients underwent 19 cervical reoperations, 12 of these patients having undergone initial surgery at another institution. The mean time to reoperation was 5·5 years. The surgical strategy in this group was to remove all parathyroid tissue in 16 patients with immediate transplantation in eight and delayed transplantation in two patients In two patients the hypertrophic remnant was reduced; 16 patients showed regression of hyperparathyroidism. Three patients died of causes unrelated to HTP II Currently, with a mean follow-up period of 3·5 years, 14 patients remain disease-free and one has persistent HPT.

Of 16 patients who underwent total parathyroidectomy with transplantation, 18 reoperations for graft reduction were required. The mean time to reoperation was 2·5 years. Hypertrophy of grafted fragments was observed in four patients Only two patients were cured by graft removal and residual parathyroid tissue after initial parathyroidectomy was suspected in five patients This was not confirmed in three (died) and two have not yet undergone reoperation. In the remaining nine patients the initial diagnosis eventually proved incorrect.

In conclusion, in considering reoperations for persistent or recurrent HPT II the correct diagnosis must be established. Reoperation after successful subtotal parathyroidectomy occurred infrequently (4·9 per cent) and was usually easily carried out with no morbidity. After total parathyroidectomy and transplantation recurrence can be due to graft-dependent disease or residual tissue within the neck or a combination of both

Total parathyroidectomy with autotransplantation for secondary hyperparathyroidism: a retrospective study

A.E. Cammack, D. Lee and R. Winney, *The Royal Infirmary, Edinburgh, UK*

Total parathyroidectomy with autotransplantation of an autologous parathyroid remnant to the forearm has now become a well established technique in the surgical management of secondary hyperparathyroidism. Between 1979 and 1986, 20 patients underwent this procedure at the Royal Infirmary of Edinburgh. Mean patient age at the time of surgery was 37·2 years with equal sex distribution and patients were followed up for a mean period of 52 months. All patients had long-standing chronic renal failure, having received renal replacement therapy for a mean of 9·8 years preoperatively and alphacalcidol for a mean of 3·3 years preoperatively. Surgery was performed for severe secondary hyperparathyroidism failing to respond to medical management with hypercalcaemia in 80 per cent, unacceptable symptoms in 65 per cent and soft tissue calcification in 45 per cent of patients. Sixteen patients had a good result from surgery with symptomatic relief, restoration of calcium homeostasis and evidence of bone healing The remaining four patients developed recurrent hyperparathyroidism with subsequent graft revision giving a good result in two and an unsatisfactory result in two There were no cases of permanent total hypoparathyroidism

Parathyroid function after surgery for Graves' disease assessed by a sensitive assay for intact (1–84) PTH

B.J. Harrison, R. Brown*, J.S. Woodhead* and C. Proye, *Department of Endocrine Surgery, University Hospital of Lille, France and *Department of Medical Biochemistry, University of Wales College of Medicine, Cardiff, UK*

Persistent hypocalcaemia (serum Ca <2 mmol/l and serum phosphate $>1{\cdot}3$ mmol/l, or serum Ca $<1{\cdot}9$ mmol/l) was recorded in four of 326 patients (1·2 per cent) who underwent bilateral thyroid surgery between January and August 1988

The fall in serum calcium following thyroidectomy for Graves' disease may reflect inadvertent removal or devascularization of parathyroid tissue, increased bone uptake of calcium, or a change in size of the intravascular compartment[1]. In contrast to previous studies we have used a sensitive and specific immunoradiometric assay for biologically active parathyroid hormone (PTH) to assess parathyroid function after surgery for primary autoimmune thyrotoxicosis

Venous blood samples after overnight fast were obtained from 11 patients (nine women and two men) immediately before and days 1–4 after thyroidectomy for Graves' disease. Serum was subsequently batch assayed to measure calcium, phosphate and PTH levels, thyroid status and renal function.

Symptomatic postoperative hypocalcaemia in two patients (group A) was associated with subnormal serum calcium and PTH levels throughout the period of study. In six asymptomatic patients (group B) the maximal postoperative incremental change in PTH ranged from -32 per cent to -67 per cent of the preoperative value; transient hypocalcaemia (serum Ca <2 mmol/l) was observed in five of these patients. In a further three asymptomatic patients (group C) the maximal postoperative incremental change in PTH ranged from $+17$ per cent to $+100$ per cent with transient hypocalcaemia recorded in two patients

In this study a low serum calcium in association with subnormal PTH values (group A) or an inappropriate fall in PTH (group B) would appear to suggest parathyroid insufficiency (usually subclinical) as the major cause of hypocalcaemia following thyroidectomy.

DNA aneuploidy in follicular neoplasms of the thyroid

L. Eleri, Z.H. Cusick, S.W.B. Ewen and N.A. Matheson, *Departments of Surgery and Pathology, Aberdeen University, Aberdeen, UK*

DNA aneuploidy is a feature of malignant disease and is a significant prognostic factor in differentiated thyroid carcinoma. Although described in some benign tumours and premalignant conditions, it has been suggested that DNA aneuploidy may be of value in distinguishing benign from malignant follicular thyroid neoplasms[1].

The nuclear DNA content of 64 follicular thyroid neoplasms (52 adenomas and 12 carcinomas) was determined by flow cytometric analysis of paraffin embedded material. technically satisfactory preparations were achieved in 57 cases. In 22 follicular adenomas DNA analysis was also performed on fresh material obtained by fine needle aspiration from the surgical specimen

An aneuploid DNA profile was obtained on analysis of fixed tissue in eight of 45 follicular adenomas (18 per cent) and three of 12 follicular carcinomas (25 per cent). DNA aneuploidy was observed in five of the 22 (23 per cent) fresh preparations from adenomas.

There were no distinguishing cytological features between follicular adenoma and carcinoma of the thyroid The only accepted criteria for the diagnosis of follicular carcinoma are the presence of vascular or capsular invasion which may be apparent only after meticulous histological examination. No difference was found in the DNA profiles of benign and malignant follicular neoplasms. Follicular neoplasia may be regarded as a single entity with a low incidence of local and distal spread

Long-term endocrine function of intraportal and intrasplenic islet autografts in cynomolgus macaques

R. Sutton, D. Gray, R.C. Turner and PJ Morris (introduced by N Dudley), *Nuffield Department of Surgery and Diabetes Research Laboratories, Oxford University, Oxford, UK*

The extent to which isolated islet transplantation in diabetic recipients restores pancreatic endocrine function may be taken to be a measure of its success

After total pancreatectomy isolated cynomolgus islets were prepared by a technique developed for human islet isolation, then autografted. Graft endocrine function was assessed by measurement of plasma glucose, insulin and glucagon following intravenous administration of bolus and low-dose continuous infusions of glucose, alanine and arginine 6 weeks, 3 months, 1 year and 2 years after grafting

Within the first 3 months animals with intraportal autografts displayed fasting normoglycaemia but mildly impaired glucose handling, with qualitatively normal though quantitatively reduced insulin and glucagon responses. Hormonal responses to alanine and arginine were also qualitatively normal, though quantitatively reduced Animals with intrasplenic autografts had poorer graft function Long-term graft function correlated with insulin responses to glucose 6 weeks after grafting ($r_s = 0{\cdot}91$, $P < 0\ 001$), two animals with intraportal grafts which have maintained fasting normoglycaemia for over 3 years consistently displayed the most nearly normal endocrine responses

These results suggest that beta cell reserve is a determinant of islet graft survival and support the feasibility of isolated islet transplantation in selected patients with diabetes mellitus

Phaeochromocytoma precipitated by premedication

D R. Goldhill, G. Tosh, A.W. Goode* and P.J. Flynn, *Anaesthetic and *Surgical Units, The London Hospital, London E1, UK*

A 67-year-old man with a 9-month history of hypertension presented for repair of an inguinal hernia. Examination was unremarkable with a maximum BP of 170/110 mmHg. Thirty minutes after intramuscular premedication with pethidine and atropine the patient felt 'unwell' and experienced retching and facial flushing. His BP was 150/90 mmHg and pulse 110 b.p.m. In the operating theatre his symptoms had receded and anaesthesia was induced. The anaesthetic included thiopentone, suxamethonium to facilitate intubation, nitrous oxide, isoflurane, droperidol, and a bupivacaine caudal. Within 15 minutes he became cyanosed, hypoxic, developed pulmonary oedema, followed later by paroxysms of hypertension (systolic BP 240 mmHg) and tachycardia (150 b.p m), with pulmonary artery occlusion pressure (PAOP) >40 mmHg in the presence of a normal CVP Urinary analysis confirmed the diagnosis of phaeochromocytoma (normetadrenaline 1100 μmol/24 h, metadrenaline 188 μmol/24 h, 3 methoxytyramine 5·8 μmol/24 h Alpha and beta blockade controlled BP, heart rate and PAOP and the pulmonary oedema and blood gases improved Eight days after the initial episode the patient developed a Gram-negative septicaemia from which he died. Post mortem confirmed a phaeochromocytoma in the right adrenal.

There are no other reports where premedication has precipitated an adverse reaction in undiagnosed phaeochromocytoma. Drugs that release histamine such as pethidine can precipitate a crisis[1], but other anaesthetic agents including droperidol[2], or surgery itself, may be triggers An idiosyncratic reaction to premedication should raise the possibility of an undiagnosed phaeochromocytoma.

Preoperative parathyroid localization by thallium isotope scintigraphy and ultrasonography: a comparative prospective study

G.L. Carlson, C.B. Clayton*, P.G. Rose† and J.R. Farndon, *Departments of Surgery, *Medical Physics and †Radiology, Royal Victoria Infirmary, Newcastle upon Tyne, UK*

Preoperative identification of the location of a parathyroid adenoma should allow reduced operating time and morbidity and perhaps a unilateral neck exploration. A variety of preoperative localization procedures have been investigated (notably thallium isotope scintigraphy and ultrasonography) without clear comparison between the investigations or demonstration of benefit to either surgeon or patient

From November 1983 to January 1988 a prospective study of 71 consecutive patients coming to first neck exploration for primary hyperparathyroidism was conducted. Both localization procedures (thallium scintigraphy and ultrasonography) were employed in each patient and a comparison with the operative findings was undertaken. Data were analysed by a combination of Mann–Whitney *U* test, decision matrix analysis and Baye's theorem as described by McNeil[1]. Both investigations had a high specificity (91 5 per cent and 94 5 per cent for thallium scanning and ultrasonography respectively), but a low sensitivity (46 6 per cent and 21 4 per cent). Despite accuracy rates for all glands of 80 per cent and 75 per cent respectively, both scans proved consistently ineffective in localizing adenomas weighing less than 500 mg, over 80 per cent of which went undetected. The low sensitivity and failure to localize the adenomas most likely to present problems for the endocrine surgeon makes both of these localization procedures of limited value in the management of patients with primary hyperparathyroidism.

Dyshormonogenetic goitres

S Vittal, M. Chandrasekaran, K. Bijakumar and R. Thirunarayanan, *Department of Surgical Endocrinology, Government General Hospital, Madras Medical College, Madras, India*

Eight patients, predominantly in the first two decades of life, with dyshormonogenetic goitre have been studied between 1986 and 1988. All patients were from a non-endemic goitre area and had raised serum thyroid stimulating hormone, an elevated radioactive iodine uptake and low serum T_3 and T_4 The diagnosis was confirmed by fine needle aspiration cytology Antithyroid antibody, both antimicrosomal and antithyroglobulin, helped to rule out thyroiditis. All except three patients were managed conservatively Surgery involved a near total thyroidectomy for cosmetic and pressure effects and one patient had a malignant lesion demonstrated by capsular infiltration and vascular invasion.

The need to identify the condition and refrain from surgery is stressed as partial thyroidectomy is inappropriate therapy

Thallium-201/technetium-99m subtraction scanning in persistent or recurrent hypercalcaemia following parathyroidectomy

N.M Wilson, J.I. Gaunt, A.J. Coakley, R.E.C. Collins and A.E. Young, *St Thomas' Hospital, London and Kent and Canterbury Hospital, Canterbury, Kent, UK*

In a consecutive series of 728 patients undergoing thallium-201/technetium-99m parathyroid subtraction scans there were 19 patients with recurrent or persistent hypercalcaemia following previous parathyroidectomy.

The scans showed a hot spot in 12 patients and nine of these underwent repeat neck exploration. In eight of these patients an abnormality was found (seven adenomas, one recurrent parathyroid carcinoma) One patient whose scan was positive had no detectable parathyroid abnormality. The three patients with positive scans who did not undergo further surgery became normocalcaemic without treatment and the diagnosis remained uncertain.

In seven patients the scan was negative. Three of these patients did not undergo further neck exploration and subsequently became normocalcaemic. Four patients underwent further surgery despite a negative scan. In none was an abnormal parathyroid gland found in the neck.

Thallium-201/technetium-99m subtraction scanning thus detected all eight persistent or recurrently abnormal parathyroid glands in the neck (sensitivity, 1·0), although one definite and three possible false positive results were recorded. Specificity was 0·67 with no false negative results. There were no complications of the investigation.

It was concluded that thallium-201/technetium-99m subtraction scanning is helpful in the management of hypercalcaemia following previous parathyroidectomy.

'Scan-directed' unilateral neck exploration for parathyroid adenoma: a legitimate approach?

C.F.J. Russell, J.D. Laird and W.R. Ferguson, *Royal Victoria Hospital, Belfast, Northern Ireland, UK*

In 75–85 per cent of patients with primary hyperparathyroidism (HPT) the underlying pathology is a solitary parathyroid adenoma. If preoperative localization studies can successfully identify the site of the adenoma, then routine exploration of the contralateral side of the neck would seem unnecessary in this large subgroup of patients.

Since 1983 we have used thallium-technetium isotope subtraction scanning for preoperative localization in all patients being submitted to operation for HPT, and since January 1985 we have adopted a policy of 'scan-directed' unilateral neck exploration for patients with a positive scintiscan and in whom an adenoma is found at the site suggested by the scan. All other patients have continued to have standard bilateral cervical exploration.

During the period 1985–88 a total of 90 individuals (74 women, 16 men) underwent 'first-time' neck exploration for HPT. In all 48 patients who had 'scan-directed' unilateral neck exploration a solitary adenoma was retrieved with return of the serum calcium to normal. Of 42 patients who had bilateral exploration 33 had a solitary adenoma, three had multigland hyperplasia and in six no abnormal parathyroid tissue was identified.

Mean operating time for the 48 patients who underwent unilateral neck exploration was 74 min; that for the group of 26 patients who had bilateral exploration for solitary adenoma following a negative or false positive scan was 95 min.

At a mean follow-up of 17·6 months (range 1–46 months) no patient who had undergone 'scan-directed' unilateral neck exploration for solitary parathyroid adenoma demonstrated persistent or recurrent hypercalcaemia.

Tc-99m RP30: a new agent for parathyroid imaging

R.E.C. Collins, A.J. Coakley, A.G. Kettle and C.P. Wells, *Department of Surgery, Kent and Canterbury Hospital, Canterbury, Kent, UK*

Thallium-201/Tc-99m pertechnetate subtraction scanning is the standard radionuclide method for localizing abnormal parathyroid glands. Tc-99m RP30 has been introduced as an alternative to Tl-201 in studying myocardial perfusion. Its use as an agent for parathyroid localization is described.

Eight patients with hyperparathyroidism have been studied with both the thallium-pertechnetate subtraction technique and also with Tc-99m RP30, and five of these have now undergone surgery. Three had solitary parathyroid adenomas which were correctly localized by both techniques; in two of these the adenomas were more readily demonstrated with Tc-99m RP30. One patient with renal hyperparathyroidism showed a similar pattern with both techniques, two of three abnormal parathyroid glands being localized and a 'false' positive thyroid adenoma. The fifth patient with metastatic parathyroid carcinoma was scanned and recurrent tumour demonstrated in the neck. This was accurately identified and at operation was easily located and removed.

These preliminary results indicate that Tc-99m RP30 may be a suitable technetium labelled alternative to Tl-201 for parathyroid localization, and is superior in some cases. Further studies are being undertaken to identify its role in parathyroid imaging.

Selective postoperative radio-iodine treatment of thyroid carcinoma

E. Paloyan, H. Jarosz, M. Davis and A.M. Lawrence, *Maywood, Illinois, USA*

In a consecutive series of 243 patients with differentiated thyroid carcinoma of follicular cell origin (Hürthle cell tumours excluded) a diagnostic imaging dose of 10 mCi ^{131}I (RAI) was administered 6 months after thyroidectomy and 4 weeks after cessation of thyroid hormone, *only* if cervical node or other evidence of metastases was present.

Patients with RAI uptake of $\geqslant$3 per cent (Group I) were treated with 150–200 mCi RAI. The total body scan was repeated 6 months later to ascertain the absence of further uptake. Patients with $<$3 per cent uptake (Group II) were treated only with thyroid hormone, as were patients with no evidence of metastases (Group III). All patients were initially treated with total thyroidectomy, and modified neck dissection if cervical lymph node metastases were present.

There were 20 patients in Group I (8·2 per cent), 62 in Group II (25·5 per cent) and 161 in Group III (66·3 per cent). The mean follow-up was 8·9 years in Group I, 8·4 years in Group II and 7·2 years in Group III. The median follow-up was 7 years for Groups I and II and 6 years for Group III. The age, sex and papillary/follicular distribution in all three groups was similar. During follow-up three patients (15 per cent) in Group I developed recurrent tumour, one patient (1·6 per cent) in Group II and none in Group III. Death rate from thyroid carcinoma was 5 per cent in Group I (one patient) and zero in Groups II and III.

In conclusion, the absence of cervical lymph node metastases or evidence of distant metastases in patients with differentiated thyroid carcinomas of follicular cell origin (Hürthle cell tumours excluded) seems to be a valid indicator that the disease is in its early stages and that in such patients (66 per cent in the present series) RAI studies and treatment are not necessary.

FNA cytology: responsibility for its diagnostic failure

K.J. Manolas, V. Primikiris, S. Tseleni-Balafouta*, N. Lyratzopoulos, D. Baxevanides and P. Diamantopoulos, *Department of Surgery, Democritus University of Thrace Medical School and *Department of Pathology, University of Athens Medical School, Greece*

FNA cytology, when applied to thyroid lesions, is incapable of establishing a correct diagnosis in about 30 per cent of cases. In this prospective clinicopathological study an attempt was made to determine whether the technique of FNA or the current cytological knowledge was responsible for the recorded diagnostic failure.

On 23 randomly selected consecutive patients out of 140 who were operated on for thyroid lesions during a 1-year period (1986–1987), a peroperative FNA cytology (perop-FNA, direct vision of the lesion) was performed in 21 as well as a preoperative one (preop-FNA, indirect technique). In 17/23 of the same cases a smear of the cut surface of the lesion was also taken after a preoperative FNA cytology had been performed. The findings of the histological examination (final correct diagnosis) were compared with those obtained through the preop-FNA, the perop-FNA and the smear examination using the χ^2 test. Clinical information regarding the thyroid lesion was provided to the cytologist when examining the preop-FNA slide but not when studying the perop-FNA or the smear slide.

It was found that although the diagnostic accuracy of all the techniques studied was still the same when compared with the histological examination (70 per cent) ($\chi^2=16{\cdot}525$, $P=0{\cdot}257\times10^{-3}$), there was no statistically significant difference ($\chi^2=10{\cdot}4$, $P>0{\cdot}1$) when the comparison was made between the three studied techniques in all possible combinations.

It is assumed that in this series of thyroid lesions the technique of preop-FNA is not responsible (in comparison with cytology evaluation) for the previously recorded relatively high percentage of diagnostic failure.

Prospective study of thyroxine therapy in the management of benign solitary thyroid nodules

P. Cheung, J. Lee and J. Boey, *Department of Surgery, University of Hong Kong, Hong Kong*

With the use of fine needle aspiration biopsy (FNA), thyroid nodules that are proven benign are often followd up without surgical intervention. It is controversial whether thyroxine therapy is effective in suppressing the growth of these nodules

We studied 62 patients with solid benign colloid nodules proven by aspiration cytology, prospectively randomized into receiving thyroxine therapy or no therapy. There were 56 women and five men. Their mean age was 39 years The mean nodule size was 3·6 cm and mean duration of occurrence was 1 year. Serum thyroxine and thyrotropin in all patients were normal Thyrotropin releasing hormone tests performed on all patients were positive indicating thyrotropin responsiveness to suppression. The patients were reviewed at 6 months, 1 year, 1·5, 2 and 3 years.

In a group of 31 patients with no thyroxine therapy, nodules decreased in size in four, remained unchanged in 15 and disappeared in two patients Six nodules increased in size with no change in pathology on repeat FNA. Three became cystic and disappeared after aspiration. One carcinoma was detected at operation for rapid increase in nodule size.

In the group of 31 patients receiving thyroxine therapy, nodules decreased in size in seven, remained unchanged in 16 and disappeared in one patient Three patients had increased nodule size Three patients developed cystic changes and nodules disappeared after aspiration. One patient had repeat aspiration biopsy showing carcinoma and underwent surgery.

Our data show that about one-third of the patients had reduction in nodule size on follow-up and that thyroxine therapy does not appear to alter the natural course of benign colloid nodules.

Decision-making for modified neck dissection in the surgery of thyroid carcinomas: cost effectiveness of routine sampling of supraclavicular nodes with frozen sections

C. Proye, A. Gontier, J.L. Quievreux, B. Carnaille, D. Camp and B.J. Harrison, *Lille, France*

Modified neck dissection (MND) is not carried out in surgery for thyroid carcinoma in the absence of grossly involved nodes, except for medullary thyroid carcinoma. Clinical node recurrence is uncommon at follow-up (5·7 per cent). Several authors report metastatic cancer in non-palpable nodes – up to 70 per cent on MND specimens The fear of overlooking occult metastatic deposits prompted us to sample all supraclavicular nodes and to rely on frozen sections (FS) to make a decision whether or not a MND should be carried out.

Of 289 consecutive patients operated on for thyroid carcinoma, 116 were submitted to supraclavicular node sampling with FS In 173 cases sampling was not done (palliative surgery, eight, lack of intraoperative diagnosis of carcinoma, 73) or for other reasons (absence of obvious nodes, 70, unavailable pathologist, 15, miscellaneous, seven). All specimens were reviewed by paraffin sections (PS)

Among the 116 patients, 23 had gross metastatic node involvement confirmed by FS^+ and PS^+, one had grossly equivocal node with FS^- and PS^+, and 92 had grossly normal nodes. In 89/92 (96·7 per cent) this was confirmed by FS^- and PS^-. In three (3·3 per cent) FS was positive, leading to MND, and PS confirmed metastatic involvement in two.

Thus, no more than 3 3 per cent of the grossly normal supraclavicular nodes contain metastases at the time of surgery. Routine node sampling with FS is not cost effective in decision-making for MND The surgeon may rely on clinical evidence of node involvement.

Size of T tubes and the radiologist

Sir

Interesting though the paper on T tube modification by Crnojevic *et al.* (*Br J Surg* 1989, **76**: 342–3) is, it is not clear from the results why the authors feel that smaller T tubes are preferable. The data clearly show that the force necessary to remove a sculpted T tube is equally low for all tube sizes between 12 and 18 French, the implication of this being that the risk of bile peritonitis is similarly low. One of the functions of the T tube is to allow access to the bile ducts for the non-operative management of retained stones. Percutaneous T tube track removal of stones[1] is simple, successful and safe but requires a T tube track of 14 French or larger. The alternatives of endoscopic removal[2] or surgery are more risky. As Crnojevic *et al.* indicate, the risk of bile peritonitis following T tube extraction is less than 1 per cent, but the risk of retained stones, even in the most experienced hands, is about 5 per cent[3]. Is it sensible on the basis of *in vitro* evidence to suggest that we should deprive ourselves of an effective method of treating a relatively common complication of bile duct surgery in order to avoid a rare complication? A compromise is necessary. Surely surgeons should use a 14 French sculpted T tube brought out subcostally in the right flank. This avoids the risks which may be associated with excessive force for the removal of the tube but allows T tube track extraction of retained stones.

Partial cholecystectomy

Sir

The article by Winkler *et al.* (*Br J Surg* 1989; **76**: 693–5) continues the endless debate on cholecystostomy. We were surprised, however, that the authors, in their discussion, omitted to mention the third option, namely, partial or subtotal cholecystectomy. This procedure was described many years ago by Torek[1] and is well described in classical operative texts[2]. Recently, Bornman *et al.*[3] described its use in 18 patients with a 'difficult' gallbladder in portal hypertension and cholecystitis. During the last 3 years we have used this technique in 14 high risk patients (APACHE II>10) who underwent emergency operation for acute cholecystitis. Three patients suffered from a bleeding tendency (portal hypertension, overdose of warfarin, chronic haemodialysis). When performing this procedure we leave a 1 cm rim of the Hartmann's pouch tissue and buttress it over the opening of the cystic duct. The exposed and often necrotic mucosa of the posterior wall is vigorously destroyed with diathermy, an omental plug is brought into the site and a suction drain is left for 24–48 h.

One patient, on chronic haemodialysis and critically ill with acalculous cholecystitis died. The others recovered without complications.

Subtotal cholecystectomy is an attractive alternative to cholecystostomy or cholecystectomy in the high risk patients with a 'difficult' gallbladder. It avoids the potential complications of cholecystostomy (fortunately not encountered by Winkler *et al.*) and achieves the objectives of cholecystectomy. It is more suitable than cholecystostomy when the gallbladder is partially or totally necrotic. Subsequent interval cholecystectomy is not required. Like cholecystostomy it is a rapid and safe procedure.

Colorectal cancer and cholecystectomy

Sir

I was disappointed to read the conclusions of the review on cholecystectomy and colorectal cancer The majority of papers in the literature have failed to find any association between colorectal cancer and cholecystectomy and of the 10 papers quoted by Moorehead and McKelvey as showing a positive correlation only 5 demonstrated an increased risk for all sites in the colon. The remainder observed an increase in certain sub-groups, e.g. females with rectal cancer[1] and such findings may be due to chance as analysing numerous subgroups for an association increases the possibility of finding a 'significant' association in one subgroup.

In the 5 papers where the whole colon was found to be at an increased risk of cancer after cholecystectomy the observed risk increases were of a moderate degree, mostly below two-fold and never exceeding three-fold and the relative risk was often not quoted or did not differ from unity.

The only prospective study[2] failed to find any increased risk in 16 773 patients undergoing cholecystectomy. The largest retrospective study[3] from California examined 5898 cases of colorectal cancer and 27 687 controls and also failed to find any increased risk of colorectal cancer after cholecystectomy yet this is not even quoted by the reviewers Moorehead and McKelvey's article is a highly selected review of the literature and many other negative studies, for example Reference 4, are not quoted.

The importance of any relationship between cholecystectomy and subsequent colon cancer is debatable. The increased risk, if real, is unlikely to be sufficient to justify the costs of screening in view of the huge number of patients who undergo cholecystectomy and would require follow-up.

Gastric cancer: a 25-year review

Sir

In their review of the incidence and management of gastric cancer in the West Midlands, Allum *et al* (*Br J Surg* 1989; **76**: 535–40) point out that 80 per cent of patients presenting with disease are considered too extensive for radical surgery, while only 0·7 per cent had Stage I disease at presentation. Higher rates of detection for early lesions reported in other studies have been attributed to widespread use of upper gastrointestinal endoscopy. Allum *et al.* recommend a change in referral patterns, with early endoscopic assessment being encouraged for patients 'with any symptoms referable to the upper gastrointestinal tract' because it is not possible to be more specific about symptoms which may be correlated with the presence or extent of malignancy.

Implementation of these recommendations would have profound consequences on the use of resources. Dyspeptic symptoms are extremely common in the community[1] and may account for 3–4 per cent of patients seen in general practitioners' surgeries[2] Because only a minority of these patients will turn out to have serious disease on investigation, the majority, quite appropriately, are treated in general practice without the need for referral or investigation. If each general practitioner working in the catchment area of a typical district general hospital were to refer a single dyspeptic patient each week for endoscopy, this would result in an unsustainable workload of over 10 000 endoscopy requests each year. Clearer guidelines are required for the selection of patients requiring investigation.

Patients' age seems to be of particular importance. A number of studies have suggested that patients under the age of 45 years do not require investigation because gastric cancer is unlikely to occur in this age group. For example, in a consecutive series of 1386 patients with dyspepsia investigated by endoscopy and radiology during 1986, Williams *et al.*[3] found no cases of oesophageal or gastric cancer in those under the age of 45. Heatley and Rathbone[4] have also recently questioned the wisdom of enthusiastic investigations in an attempt to diagnose every case of early gastric cancer. Indeed, many of the recommendations about the use of H_2-receptor antagonists have been developed because of anxieties about 'missing' cancer by masking symptoms of ulcerating lesions and creating diagnostic delay. The suggestion that these agents should not be used before an endoscopic or radiological diagnosis is obtained would also lead to overwhelming numbers of hospital referrals. Investigation is, of course, required when symptoms fail to respond or recur after a course of treatment, with increasing age being a guide to the urgency of investigation.

In the absence of diagnostic symptoms or symptom complexes, the identification of early gastric cancer remains a challenge, but one which is unlikely to be met adequately by indiscriminate investigation of all patients with dyspeptic symptoms.

Perforated peptic ulcer

Sir

We read with interest the article 'Operative mortality after perforated peptic ulcer' by Messrs Ball, Thomas and Evans (*Br J Surg* 1989; **76**: 521–2). The authors identified a group of elderly patients for whom surgery carries a high risk of mortality and suggested that the role of conservative treatment should be evaluated in this group of patients.

We recently conducted a randomized controlled trial comparing expectant treatment with immediate surgery in patients with perforated peptic ulcers[1]. Over a 13-month period 83 patients were randomized, 40 to conservative treatment and 43 to immediate surgery. The patients in the conservative group were re-examined by a senior member of staff at 12-hourly intervals and were operated on if there was no improvement. Of the 40 patients in this group, 11 (28 per cent) required operation. The mortality rate (5 per cent in each group) and morbidity were similar in the two treatment groups. The patient's age was an important determinant of successful conservative treatment; all eight patients under 40 years of age and 18 out of 23 aged between 40 and 70 sealed their perforation spontaneously, whereas only three out of nine patients over 70 years of age had spontaneous sealing ($P < 0.05$).

Elderly patients with perforated peptic ulcers are less likely to respond to non-operative treatment. These patients withstand continued intra-abdominal sepsis poorly. Although the risk of surgery is high, urgent laparotomy after adequate resuscitation offers the best chance of a successful outcome.

Changing concepts in renovascular surgery

Letter 1

Sir

We read with interest the Leading Article by Bergentz and colleagues (*Br J Surg* 1989; **76**: 429–30). A further evolving concept which deserves mention, but which few authors have focused upon, is the approach one should adopt to renovascular problems in the presence of an abdominal aortic aneurysm.

We recently reviewed our series of 142 elective aortic aneurysms over a 40-month period and noted that 19 patients (13·4 per cent) required combined aneurysm surgery with renal artery reconstruction. Eight of these patients underwent surgery for the presence of one or more renal arteries arising from the aneurysm. Of the remaining 11 patients, nine (47·4 per cent of the 19 patients) required surgery for renal insufficiency, while in two cases the indication was clinically significant uncontrollable hypertension. Like our colleagues, we also had disappointing results with percutaneous transluminal angioplasty, particularly with ostium lesions.

Nine of the 19 patients underwent bilateral renal artery surgery, resulting in a total of 28 vessels being operated upon in the series. Main renal revascularization procedures included trans-aortic renal artery endarterectomy (TEA) alone in ten arteries or in combination with renal artery reimplantation in three arteries, renal artery reimplantation alone in eight arteries, and renal artery bypass grafting in four arteries utilizing a 5-mm thin-walled ePTFE graft.

We had one death postoperatively in the series owing to a disseminated intravascular coagulation. One patient developed a hemiparesis while a second patient suffered a myocardial infarction and a third patient suffered a pulmonary embolus. Both of the latter patients made a good recovery. Four patients suffered a temporary deterioration in renal function but had returned to their preoperative creatinine levels at 2-month follow-up. Long-term follow-up (mean 17 months) revealed that nine of 13 patients noted to be hypertensive on preoperative evaluation were cured or improved after surgery according to the criteria proposed by Dean *et al.*[1]. This included the two patients whose indication for operation was hypertension. In three patients hypertension was unchanged postoperatively, while it worsened in one patient requiring increased medication. Normal renal function was maintained in the 10 patients who had normal preoperative serum creatinine levels. No patient undergoing the combined procedure required permanent haemodialysis.

While our series is small, we feel that with careful preoperative assessment and appropriate surgical technique, combined abdominal aortic aneurysm resection and renal revascularization can be performed with a low complication rate. Until such time as the results of the prospective trial by Bergentz and colleagues comparing reconstructive surgery and percutaneous transluminal angioplasty are available, patients should not be denied this combined procedure, particularly where preservation of renal function is a primary concern.

Letter 2

Sir

We read with interest the recent review article on renovascular surgery by Bergentz and colleagues (*Br J Surg* 1989, **76**: 429–30). We support their reccommendations for aggressive surgical management of acute renal artery thrombosis even in elderly patients.

An 80-year-old lady, who had been well apart from myocardial infarction 11 years previously, was referred by her family practitioner because of deteriorating renal function in association with hypertension. The blood pressure was poorly responsive to a combination of enalapril 2·5 mg and frusemide 40 mg (with potassium supplementation). Examination revealed a blood pressure of 180/90 mmHg supine and 170/90 mmHg upright. There was an ejection systolic murmur and an epigastric and femoral bruit, but pedal pulses were palpable. Investigations showed a urea concentration of 27·3 mmol/l, creatinine concentration of 446 μmol/l and potassium concentration of 5·7 mmol/l. Isotope estimation of glomerular filtration rate was 16 ml/min and demonstrated a non-functioning left kidney.

When the patient was telephoned to discontinue her potassium supplementation, she informed us that she had passed no urine for 20 h. She was seen urgently in the emergency department. She was in pulmonary oedema, but complained of no loin pain. Urea concentration was 31·6 mmol/l, creatinine concentration 599 μmol/l and potassium concentration 6·2 mmol/l. Ultrasound scan demonstrated an atrophic (6 cm) left kidney and a 9·5 cm right kidney. Following acute haemodialysis, an aortogram demonstrated occlusion of the left renal artery at its origin and of the right renal artery 2 cm from the origin. A gastroduodenal–renal artery end-to-end anastomosis was performed and she began to diurese during the surgical procedure. She required no further dialysis or hypotensive medications. At the time of discharge her creatinine concentration was 240 μmol/l.

We would like to draw attention to the role of gastroduodenal–renal artery bypass. In the elderly and hypertensive population, the aorta may be severely diseased and not easily amenable to renal artery bypass. Using gastroduodenal – (or hepatorenal) bypass will spare the patient the morbidity associated with aortic surgery.

In the setting of hypertension and moderate renal insufficiency, the onset of complete anuria should raise the suspicion of acute renal artery occlusion (either bilaterally, or to a solitary functioning kidney). Timely surgical intervention may obviate the need for long term renal replacement therapy in these patients.

Extending surgical audit

Sir

Mr Macintyre is right to stress the importance of extending surgical audit to include data relating to the important aspects of outcome[1]. At present, most audits concentrate upon easily collected in-patient data rather than more complex issues such as survival, disease recurrence and quality of life indicators, information which may be of far greater importance to the patient. A major concern with the recent government proposals[2] is that, in the absence of data about the eventual outcome, there will be too much emphasis placed on data relating to resource management or short term indicators. It is not inconceivable that some of these measures are inversely related to long term outcomes To make decisions about referral or resource allocation based upon an audit which omits such indicators is an incentive to select more simple and cheaper treatments, possibly to the detriment of long term results

Full audit of follow-up data from out-patient clinics or postal questionnaires must be the ultimate aim, but it will take many years to implement, and many more before useful results emerge. In the mean time in-patient audit provides invaluable information for surgeons and managers. But can audit really be used as 'proven results' to guide patient and GP in the choice of referral hospital, firm or consultant? This would appear to raise a number of difficulties Results of audit are usually classified by diagnosis or operation and these may not be predictable at the time of initial referral. Information about outcome would have to be linked to data about patient mix and selection to prevent bias against those treating poor risk patients. Even if appropriate and accurate data could be delivered to the decision maker there would be few operations that are performed frequently enough for meaningful confidence limits to be placed on the incidence of complications or recurrence. If two surgeons have observed mortality rates of 5 and 10 per cent for the same operation they would have to do about 200 cases each before the difference would be significant. To demonstrate that poor results from one of a large number of units is anything other than a chance finding requires complex calculations on a large quantity of simplified data[3]

Audit may improve surgical practice but it seems unlikely that it will be able to furnish much in the way of hard statistical evidence as to the relative merits of different units. Medical students today are taught the importance of properly controlled and randomized trials Are we to see these principles eroded in favour of referral to the surgeon with the best result over the last 20 cases, or will general practitioners begin multi-centre, controlled trials with randomized referrals to different hospitals? Until better information is available it would seem preferable for referral patterns to continue to be governed primarily by 'personality and geographical proximity', rather than by inappropriate data, financial incentives and advertising

Paralytic ileus: response to naloxone

Sir

Therapeutic use of opiates may be accompanied by adverse effects on smooth muscle function. For example, acute urinary retention may be precipitated by parenteral opiates[1] or sublingual buprenorphine[2]. Competitive receptor blockade with naloxone[3] will reverse many of these provoked retentions without loss of analgesia. Involvement of μ opiate receptors in other nerve plexes is less well documented. Opiates have been reported to cause paralytic ileus, but this association is rarely considered and therefore the effect of naloxone is unknown. We report the case of a 51-year-old man with a small cell carcinoma of unknown primary origin. The patient commenced on oral morphine sulphate tablets (MST) 30 mg tds 1 week before he was readmitted acutely with a 5-day history of absolute constipation On examination, he was found to have diffuse abdominal tenderness associated with ascites and a paralytic ileus As the MST might have contributed to his condition, 0·8 mg naloxone was administered intravenously. Bowel sounds returned dramatically within 1 min and he defaecated massively on three occasions within the next 10 min. This was accompanied by total relief of his diffuse abdominal pain.

Paralytic ileus is a frequent complication of many operations and its aetiology is often multifactorial. However, both exogenous and endogenous opiates may be implicated in its genesis As reversal is rapid, this report may suggest an acceptable alternative therapy for selected patients with paralytic ileus.

Pleomorphic adenomas of the parotid salivary gland

Sir

I read Mr H. Lawson's article on capsular penetration and perforation in pleomorphic adenomas of the parotid salivary gland with great interest (*Br J Surg* 1989, **76**: 594–6). He kindly refers in his introduction to my recent article[1]

Unfortunately, I am misquoted. The figure of 1·6 per cent refers to rate of accidental rupture of the tumour (one of 64 cases), and not to recurrence rate. There were no recurrences and are still none, in a series which has grown to 74 new pleomorphic adenomas with a median follow-up of 5 years.

I am quoted as advocating removal of the tumour with only a covering of normal parotid This confusing statement is presumably a typographical error. It would be correct to say that I advocate a small covering of normal parotid wherever possible.

My concern about Mr Lawson's study is that he refocuses attention on the observation of capsular penetration reported by Patey and Thackeray in 1957. This oft-quoted observation seems to have blinded most surgeons from accepting the obvious, this being that, with rare exceptions, recurrence of a pleomorphic adenoma is due to a macroscopic accidental rupture of the capsule, basically a technical error. Once this is more widely recognized, the observation of microscopic penetration of the capsule will be seen as an interesting but largely irrelevant observation and the controversy of formal superficial parotidectomy against enucleation will cease

The precise method of removal is unimportant provided that the capsule is not ruptured. In practice this is best achieved by early exposure of the facial nerve and removal of the tumour with a modest covering of parotid In deep tumours and those in contact with the nerve, this will not be possible, while in very superficial or peripheral tumours a careful local dissection may well be the procedure of choice.

Whatever the situation, a very low recurrence rate can be anticipated provided the tumour is removed intact.

Sister Mary Joseph's nodule

Sir

The article by Heatley and Toner (*Br J Surg* 1989; **76**: 728–9) in the July issue of the journal states that metastasis to the umbilical skin was first described by Storer, and is often known as Sister Mary Joseph's nodule I would like to point out that Walshe[1] in 1846 reported that Tanchov in reviewing the data from the Mortuary Registers of Paris and two adjacent *arrondissements* found 9118 deaths from cancer from 1830 to 1840 inclusive, and found that the umbilicus was involved in two cases.

Lage[2] in 1847 reported a case of colon cancer with umbilical metastasis. Storer[3] in 1864 reported on a lady who at autopsy was found to have carcinomatosis from carcinoma of the stomach with umbilical metastasis.

Sister Mary Joseph[4] (1856–1939) was superintendent of St. Mary's Hospital when she drew the attention of Dr William Mayo to this sign of intra-abdominal malignancy. The eponym, Sister Mary Joseph's nodule, was first described by Hamilton Bailey in the 11th edition of his book on physical signs in clinical surgery in 1949, and has since been used by generations of physicians.

Oesophageal transection for variceal haemorrhage

Sir

Jenkins and Shields (*Br J Surg* 1989; **76** 49–51) correctly question the efficacy of emergency oesophageal transection in patients with compromised liver function who failed sclerotherapy Mortality in their patients with poor liver function (Child's C) was 100 per cent, while half of Child's B grade patients died. The authors do not, however, define sclerotherapy failure nor does the data allow an accurate assessment of the number of acute injections attempted or the delay prior to an extensive devascularization of the lower oesophagus and proximal stomach.

The limitations of repeated injection sclerotherapy in continued acute variceal bleeding have previously been emphasized by our group[1]. The mortality rate in a small subgroup of patients (12 of 66) who required more than two injection sessions for control of bleeding was 66 per cent and a prohibitive 89 per cent when Child's A patients were excluded. This was significantly higher than the 21 per cent mortality rate in the group who stopped bleeding after one or two injection sessions. Further analysis failed to identify factors which predicted continued bleeding. These results stressed the limitations of repeated sclerotherapy in controlling continued variceal bleeding, and raised the unresolved question of how best to manage these patients.

The extensive devascularization procedure used by Jenkins and co-workers may explain the poor results achieved in this study and one may speculate whether a lesser procedure, such as simple oesophageal transection, would have been better tolerated Data on this issue are urgently needed. However, the decision to operate on these poor-risk patients is often difficult, bearing in mind their dismal prognosis even when control of variceal bleeding is achieved. This poses the difficult ethical question of when treatment should be withdrawn in selected patients. In this respect a prognostic index may be helpful in selecting patients for further active treatment.

Outpatient paediatric surgery

Sir

With reference to the article on outpatient inguinal hernia repair in children by Mr Mejdahl and colleagues (*Br J Surg* 1989; **76**: 406–7), it may be appropriate to commemorate the 50th anniversary of a forgotten pioneer article in this field. In 1938, Gertrude Herzfeld[1], surgeon to the Royal Edinburgh Hospital for Sick Children, reviewing her experience with 1000 inguinal herniorraphies in children, stated· 'It is important in operating on young infants not to keep them in hospital. A baby taken suddenly from its home environment, however bad, invariably loses weight, and is upset by admission to hospital. It is my usual practice to send the baby home some 2 hours or so after operation, and I have never had cause to regret this procedure'

Taking into account the progress made since that time and a personal experience of 4000 outpatient paediatric hernia repairs and appendicectomies[2], we consider the time ripe to propose appendicectomy as an additional day-care procedure In our own series of 1921 outpatient appendicectomies the readmission rate was 1·2 per cent for wound infection, fever and stool problems. Relaparotomy became necessary in three cases, mortality was nil. As a rule, complications of appendicectomy should not occur before postoperative days 3 to 7, by which time many children have already been discharged.

Surgeons have been slow following the concepts of Herzfeld's report. Day-stay appendicectomy will require surgical and anesthesetic techniques, preoperative and postoperative examination, patient selection, instruction and follow-up service in excess of routine standards. Outpatient paediatric surgery provides a stimulus to strive for professional and humane competence

Book reviews

A Colour Atlas of Faecal Incontinence and Complete Rectal Prolapse

M. M. Henry and N. H. Porter. 267 × 203 mm. Pp. 57 Illustrated. 1988 London. Wolfe Medical Publications Ltd. £19.00.

This is one of a series which sets out to illustrate single operations. In this case, three operations are covered, postanal repair, external anal sphincter repair and the Ivalon sponge repair for total rectal prolapse. The atlas is predominantly an illustration of the operations, step-by-step.

The photography and illustrations of postanal repair and external sphincter repair are quite remarkable for their clarity in what is a difficult area The standard of illustration is not as good for the Ivalon sponge repair, which makes it difficult to follow this operation The whole book is beautifully produced and doubtless will be welcomed by those collecting this series

Chronic Pain

R. D. France and K. R. R. Krishnan. 152 × 241 mm. Pp. 542 Not illustrated. 1988. Washington, DC. American Psychiatric Inc £19.50.

This book is written by two American psychiatrists primarily for American psychiatrists with an interest in pain. Its purpose is to cover the subject from basic science to clinical management with an emphasis on psychological aspects. The book fulfils this aim and psychiatrists and clinical psychologists working in this field would find much of interest in it. It also covers drug therapy, physiotherapy, physical therapies such as nerve blocks and electrical stimulation, and the nursing of patients with chronic pain problems. The book gives emphasis to 'Multi-disciplinary Evaluation and Multi Modal treatments'. Unfortunately the results of such a grand design are assessment procedures and management programmes of such complexity that they are relevant only to highly specialized centres and are far too time-consuming for the average doctor who only sees a few patients with chronic pain every year This is not a book for the average doctor who wishes a short succinct introduction to the subject of chronic pain.

Lives of the Fellows of the Royal College of Surgeons of England 1974–1982

E. H. Cornelius, S. F. Taylor. 240 × 155 mm. Pp 429. 1988. London: Royal College of Surgeons of England. £35.00.

In the 8 years from 1974 to 1982 the College lost its reigning President, Sir Alan Parks, and three past Presidents: Sir Cecil Wakeley, Sir James Paterson Ross and Lord Brock. Deceased Honorary Fellows included HRH the Duke of Gloucester, the Marquess of Exeter, and such distinguished overseas surgeons as John Cid dos Santos, J. Englebert Dunphy, John Loewenthal, Wilder Penfield, Pietro Valdoni and Owen Wangensteen. In our Fellowship before those years, there were many household names in surgery, who many will remember with affection.

Younger men of distinction were taken, too. The long list of men we knew, and others whose lives after diploma day are less fully recorded, are all here and each with a careful, thoughtful tribute. The editors have worked kindly and well to set this fine memorial to our colleagues who are gone ahead

Surgical Pathology. 2nd ed.

W. Coulson. 178 × 254 mm. Illustrated. 1988. Philadelphia J. B Lippincott Co. £125.00.

This is a large, two-volume book with approximately 1700 pages. It deals with surgical pathology from the point of view of the histopathologist. It is copiously illustrated with well-produced photomicrographs, which are all in black-and-white.

Dr Coulson has written a number of the chapters but has drawn widely on his colleagues in pathology, especially those from Los Angeles, to write individual chapters. The overall standard is good but some subjects are dealt with rather superficially, which is surprising for a book of such length.

This is a book for the pathologist, written by pathologists, and it may find its way into departmental libraries in pathology departments It is certainly not the type of book which would be bought by practising surgeons, though they may occasionally wish to use it as a source of reference, particularly since the reference section in each chapter is very full.

Manual of Surgical Therapeutics. 7th ed.

R. E. Condon, L. M. Nyhus. 220 × 135 mm Pp. 417. Illustrated. 1988 Boston· Little, Brown & Co. £9.95.

This book offers rapid access to a large variety of surgical problems encountered in both the emergency and elective situations. I enjoyed reading it thoroughly and feel it is relevant to all surgeons in training, especially to those who have to deal with emergencies.

The book has many authors – all contributing towards their own specialities in this manual. I think there is a genuine need for a book which does concentrate on the surgical therapeutics with regard to non-operative management of surgical patients. As stated in the Preface, the book is not meant to be a complete or systemic representation of all of surgery but instead the aim is to bring together in one volume all the material that is needed for quick review by surgeons faced with the clinical problem when there is not time to do otherwise

Generally speaking, I think this is a valuable contribution to medical education and the practice of surgery.

Atlas of CO_2 Laser Surgical Technique

I Lanzafame 203 × 279 mm Pp. 286. Illustrated. 1988 St Louis Ishiyaku EuroAmerica Inc. $145 00

Most surgeons have wondered at some time during the 20 years that CO_2 lasers have been available if they would have a use for such an instrument in their operating theatre. Much of the literature about lasers is anecdotal and unsubstantiated, so surgeons understandably feel they need to see the instrument in use before they can make a decision This can be difficult to arrange, so a substitute is provided by this book with its large format and 400-plus photographs of lasers being used for a wide range of operations in general surgery together with pictures of the results. There are also sections on physics, safety, detailed descriptions of the techniques and extensive references

Liver resection is the principal operation for which surgeons wish for something better than the scalpel. Unfortunately, however, here the CO_2 laser fails to deliver, for that is the only operation that the authors accept is better done by conventional methods. For each of the other operations a list of advantages of the laser is set out, and these include greater precision of cutting, less blood loss, sterilization of infected tissue, efficient killing of malignant cells (therefore less tumour recurrence), sealing of lymphatics and less postoperative pain. This sounds impressive but is mostly unproven.

The disadvantages of laser surgery are not mentioned in this book, which is written by American enthusiasts. These are that the operations take longer, the instruments are awkward to use, there are possible dangers to patient and staff, they produce smoke, and they are expensive. Also, is the blood loss in most of the operations mentioned really a problem, can infected lesions not be as effectively dealt with by other methods today, is local recurrence significantly reduced and are the scars as good with the laser? Enthusiasts overlook such questions.

Will general surgeons wish to use lasers after reading this book? Those who have already decided to start laser surgery will obtain useful hints from this book, but most general surgeons will not be encouraged to change. However, it is easy to become complacent about such matters as blood loss and postoperative pain, and if the stimulation of seeing this new technique does not result in a change to using the laser, at least it should encourage a reassessment of present results in these areas to make sure that the existing techniques cannot be bettered.

Outpatient Surgery

G. J. Hill. 178 × 267 mm. Pp. 696. Illustrated 1988. Philadelphia: W. B Saunders. £37.50.

That this book is in a third edition reflects the vigour of the North American movement to day-case (ambulatory) surgery and technical procedures. The book is written by a galaxy of distinguished authors, all but one of whom are from North America.

The book is eclectic with an interesting mixture of topics reflecting American rather than European practice and organization Somehow I sensed that the generalist is rather more alive in some American situations than in the UK. Because each section is written by specialists there are inevitable overlaps and repetitions; indeed, some of these territorial inexactitudes probably represent demarcation disputes! But they also give alternative views of commonplace problems, for example suturing a full thickness eyelid wound, which require special technical care Demarcation disputes are not always malign and in this book represent pride in individual specialities rather than atavism.

The book crosses the Atlantic well and will be useful in many of our hospitals; your hospital copy will be best kept as a bench book close to the Accident and Emergency operating room. Overall, however, the book does fit the American more easily than the contemporary UK scene, though no doubt in 20 years our practice will be similar to that in America today. I quote.

> The spectrum of (day-case) surgical procedures thus ranges from skin biopsies in the physician's office to cholecystectomy performed in the hospital.

Day-case inguinal herniorrhaphy is still considered too adventurous for many British surgeons; obviously the NHS budget still has too much fat in it . . or does humanity still outweigh economics in British surgeons' morality?

I recommend this as a good, sensible and comprehensive text about outpatient surgery, just as the title suggests.

Erratum

'Antibiotic prophylaxis and postoperative sepsis after cholecystectomy' by D. Menzies and H. Ellis, *Br J Surg* 1989; **76**: 764, Table 1. The headings in this table were all displaced one position to the left. We apologize for this error. The letter is reproduced in full below.

Antibiotic prophylaxis and postoperative sepsis after cholecystectomy

Sir

The article by Wells *et al.* (*Br J Surg* 1989; **76**: 374–7), concerning the relationship between bile colonization, high-risk factors and postoperative sepsis, mirrored the results of a consecutive series of 504 cholecystectomies from the Westminster Surgical Unit[1] (*Table 1*).

Table 1 *Bile infection and wound infection in a consecutive series of 504 cholecystectomies*

	Positive bile culture	Positive bile culture with wound infection	Same organism in bile and wound infection	Negative bile culture with wound infection	Negative bile culture with *S. aureus* wound infection
Prophylactic antibiotics ($n=379$)	79/379 (21)	12/79 (15)	8/12 (66)	14/300 (5)	9/14 (64)
No antibiotics ($n=125$)	21/125 (17)	9/21 (43)	5/9 (56)	23/104 (22)	16/23 (69)
Significance (χ^2)	—	$P<0.01$	—	$P<0.001$	—

Values in parentheses are percentages

Wells *et al.* conclude that, despite prophylactic antibiotics, bile colonization remains the major factor associated with postoperative sepsis This is in agreement with our results They did not compare their study group with a control group, justifiably, in view of the current body of evidence that demonstrates the value of antibiotics in biliary surgery

In our own analysis the most common cause of wound infection was *Staphylococcus aureus*, not biliary organisms, for those patients receiving no prophylaxis In those patients who received antibiotic prophylaxis, the incidence of *S. aureus* wound infections was significantly reduced

We would suggest that it is because of, not despite, antibiotics that bile colonization is the major factor associated with postoperative sepsis. This is more in line with the study by Willis *et al.*[2] who showed that in the absence of prophylactic antibiotics (*not* in the presence of prophylaxis, as quoted by Wells) wound infections were more commonly exogenous, a finding confirmed by Van Leeuwen[3].

It is because of this that we would agree with Wells in concluding that selective administration of antibiotics is inadvisable, and would add that, in choosing a suitable antibiotic, one should be chosen that has an anti-staphylococcal activity

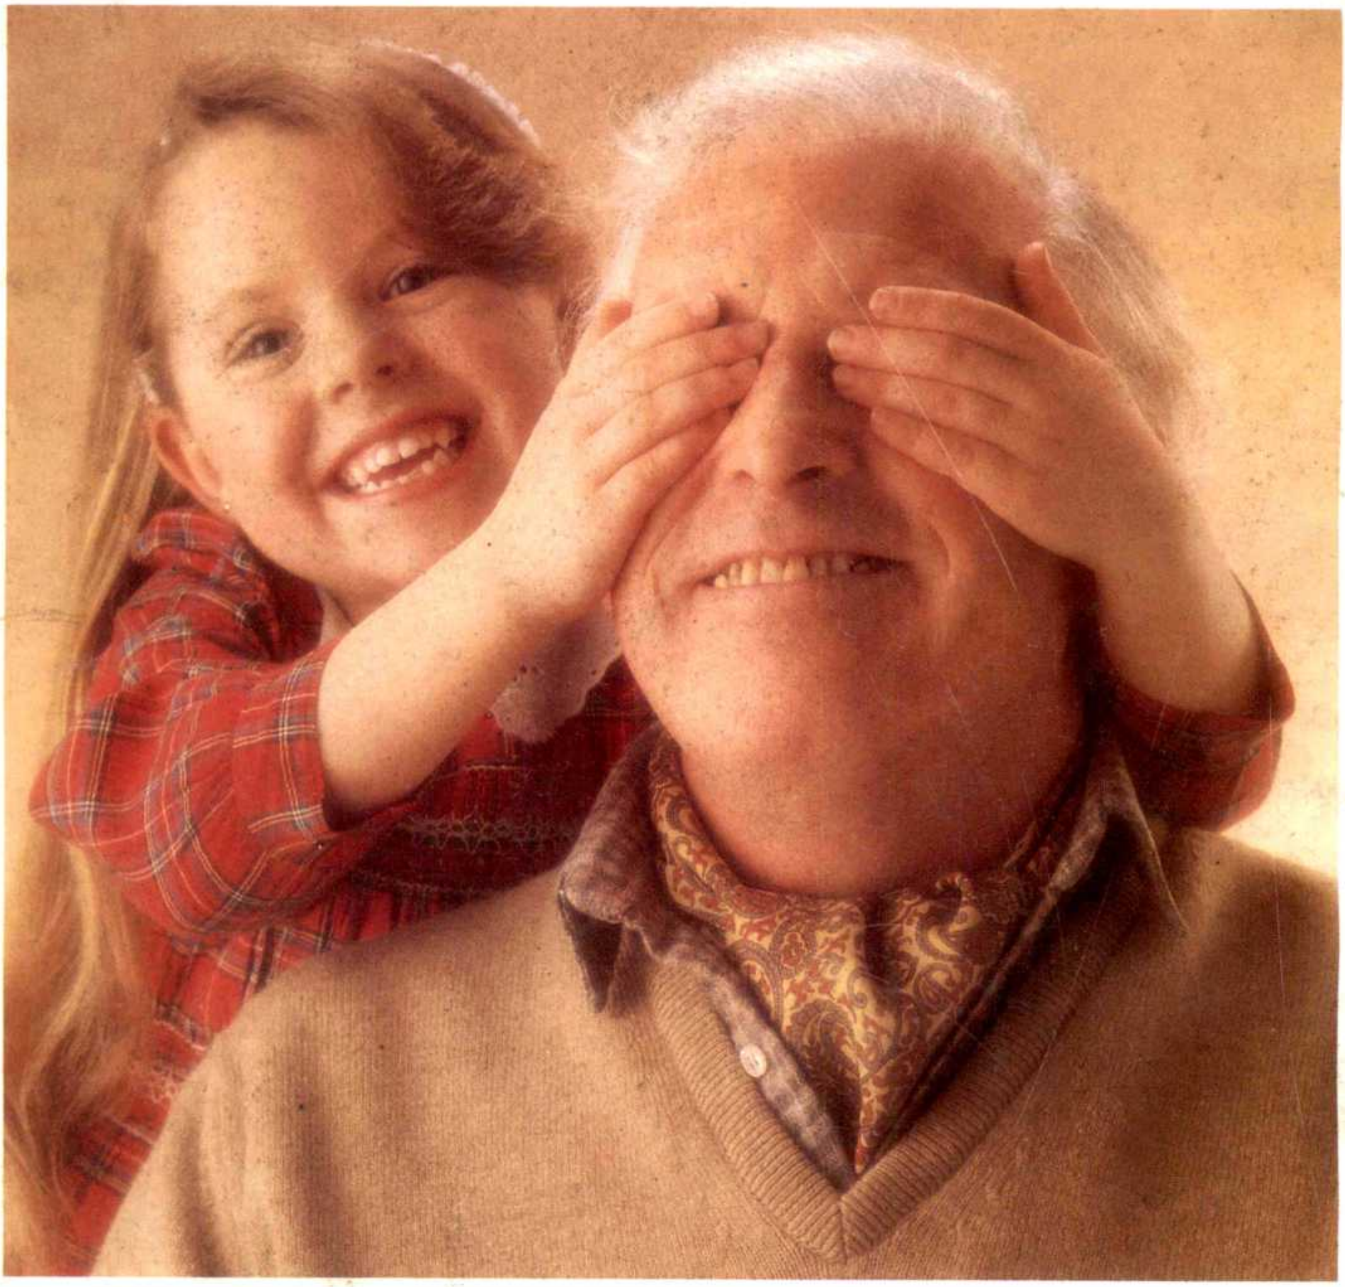
A30 **Information for Authors**

Guess which prostate cancer treatment most patients would choose.



In a recent study[1], 57 prostate cancer patients were invited to participate in choosing their treatment. All were informed that the two treatments available, sub-capsular orchidectomy or 'Zoladex', were similar in efficacy and side effects. 49 of the patients (86%) opted for 'Zoladex'.

A recent trial[2] has established the equivalence of 'Zoladex' to orchidectomy.

Zoladex

goserelin

Effective therapy without surgery.

▼ 'ZOLADEX' PRESCRIBING NOTES.

Use: Prostate cancer suitable for hormonal manipulation. **Presentation:** A sterile depot containing goserelin 3.6mg. **Dosage and administration:** One depot injected subcutaneously into the anterior abdominal wall every 28 days. **Precautions:** Care with patients at particular risk of developing ureteric obstruction or spinal cord compression. Consider initial use of an anti-androgen at the start of therapy. **Side effects:** Hot flushes, decrease in libido and occasional breast swelling and tenderness. Skin rashes (generally mild). Occasional mild bruising at injection site. Initial transient increase in serum testosterone may cause temporary increase in bone pain. **Product licence number:** 29/0198. **Basic NHS Price:** £114.00 per depot. 'Zoladex' is a trademark. Further information is available from: ICI Pharmaceuticals (UK), Southbank, Alderley Park, Macclesfield, Cheshire SK10 4TF.

A must for all surgeons who practice vascular surgery

G. Heberer, University of Munich;
R. J. A. M. van Dongen, University of Amsterdam (Eds.)

new

Vascular Surgery

With the assistance of K. W. Jauch, H. Stiegler
Foreword by D. C. Sabiston
With contributions by numerous experts

1989. XVI, 816 pp. 660 figs., mostly in color in
1457 sep. illus. Hardcover £213.00
ISBN 3-540-18280-2

From the foreword by David C. Sabiston:
"In this unusually thorough yet concise and superbly written monograph, the authors have brought the state of the art in this field to a new standard of **excellence...** It can be confidently predicted that this monograph will become a world-wide standard by which **all** other similar works will be compared, and it is regarded as an essential text for all surgeons who practice vascular surgery."

Contents: History of Vascular Surgery. - Anatomy. - Hemodynamic Aspects in Vascular Surgery. - Technique of Vascular Surgery. - Vascular Reconstruction. - Microvascular Surgery. - Conservative and Radiologic Measures. - Intraoperative and Postoperative Assessment. - Documentation and Statistics. - Postoperative Complications. - Anesthesia in Vascular Surgery. - Vascular Deformities. - Peripheral and Abdominal Arterial Injuries. - Replantation of Peripheral Body Parts (Microreplantation). - Arterial Aneurysms. - Acute Obstructive Disease of the Extremities. - Occlusive Disease in the Lower Extremities. - Occlusions of the Supra-aortic Branches. - Chronic Occlusions of Upper Extremity Arteries. - Extra-anatomic Bypasses in Chronic Arterial Occlusive Disease (Infections, Patients at Risk). - Compression Syndromes. - Revascularization of the Visceral Arteries. - Renal Artery Occlusive Disease. - Supplementary and Palliative Procedures of the Extremities. - Vascular Access for Hemodialysis. - Further Arterial Procedures. - Surgery of Veins. - Surgery for Portal Hypertension. - Surgery of Lymphedema. - Subject Index.

A certain standardization has now been introduced into the operative techniques of vascular surgery after the stormy developments of the last few decades. It is to make the knowledge gained in those years more widely available that this operative manual **Vascular Surgery** has been compiled. It contains contributions from numerous authors at European centers of vascular surgery.
Both the young surgeon in training and the more experienced surgeon continuing training will find in this book all the necessary instructions for the diagnosis, preoperative preparation, and reconstructive surgery of the arteries, veins, and lymph vessels (the coronary vessels are excluded from this book, as they are covered separately). The chapters are structured according to a uniform scheme, with sections on special anatomy, indications, surgical tactics, and operative technique. The dynamics of individual operations are illustrated, step by step, in sequences of clear, multicolored figures. Aftercare and alternative angiologic therapies are covered.
The vascular surgeon will find here new variants on the usual operative techniques and much stimulating discussion of complications and their prevention and treatment.

The Centenary of the Polish Association of Surgeons and the Bicentenary of the Academic Surgery in Poland

Academic surgery in Poland had its beginnings in the Chair of Anatomy, Surgery and Obstetrics founded in the Jagiellonian University, Cracow in the late 18th century. The Jagiellonian University was founded in 1364 in Cracow, then the capital of Poland. The University flourished throughout the Renaissance and among the greatest graduates of the Medical Faculty was Mikołaj Kopernik (1473–1543), famous physician and astronomer. The importance of the University declined when the capital was effectively moved to Warsaw by King Sigismund III in 1609. However social and cultural reforms in the mid-18th century led to the creation in Poland of the first European Ministry of Education. The consequent re-invigoration of the Jagiellonian University led to the establishment of the Department of Surgery under the supervision of Professor Rafał Czerwiakowski (1743–1816).

Czerwiakowski was not only an outstanding surgeon but an important teacher who introduced the autopsy to clinical teaching and who also wrote a textbook of surgery and numerous research papers. The most splendid development of the University Department of Surgery was initiated by Ludwik Bierkowski (1801–1860) who used ether anaesthesia for the first time in Poland on 6 February 1847. This very talented educator developed the teaching of surgery, and compiled and wrote an atlas of anatomy, a textbook of surgical techniques and numerous papers in which he devoted much attention to medical ethics. His successor, Antoni Bryk (1820–1881), pioneered antiseptic surgery in Poland. Following Bryk, Jan Mikulicz-Radecki (1859–1905), a favourite student of Billroth, was appointed Professor.

Professor Mikulicz's arrival in Cracow evoked certain anxiety, as he was reputed to have an 'incorrect command of the Polish language'. Yet in his inaugural address Mikulicz emphasized that '... a faculty of poor knowledge of the Polish language is charged upon me; yet this language is the mother tongue for me and for all of you gentlemen alike ...'[1]. During his tenure of the Chair in Cracow, Mikulicz invented new operative techniques and designed surgical equipment and instruments which are still in use today. He applied a new technique of gastric resection and in February 1887 performed pyloroplasty, known as a Heinecke-Mikulicz method. In Cracow he invented alimentary tract endoscopy, laying the foundations for the modern gastroenterological diagnostics and was the first to describe the endoscopic image of effectively treated gastric cancer[2], and became known as the 'father of alimentary tract endoscopy'. His endeavours to fund a new building for the Department were abortive, so in exasperation he resigned and moved to Krolewiec and later to Wroclaw.

His equally famous successor Ludwik Rydygier (1850–1920), appointed in 1887, had gained world renown on 16 November 1880 when he performed a gastrectomy in a patient with gastric cancer, thus becoming the second surgeon to do so after Pean and preceding Billroth. On 21 November 1881 he was the first to resect part of the stomach for peptic ulcer, paving the way for the routine surgical management for acid/pepsin disease.

His pioneering method, opening the possibilities for peptic ulcer surgery, initially did not find any followers, and was not given a proper credit in the literature. It was commented with a single statement: 'and hopefully, the last'[3]. Rydygier was the first surgeon ever to employ gastroenterostomy for ulcer pyloric stenosis on 13 March 1884 and introduced important new methods in biliary, vascular and urological surgery while in Cracow. He succeeded in his efforts to obtain permission to build new premises to house the Department. The construction work took less than a year and, in October 1889, the first Congress of Polish Surgeons was organized simultaneously with the opening of the Department. Rydygier was active in Cracow for 10 years, and later he and his entire team of assistants moved to Lvov where he was appointed to the Chair of Surgery at the local university.

Alfred Obaliński (1843–1898), the immediate successor to Rydygier, became famous for being the first surgeon to use the Giglic saw in cranioplasty[4]. He was also the first surgeon in Poland to present, on 11 February 1896, a radiograph of a dislocated elbow made in the laboratory of Professor Olszewski from the Jagiellonian University who, in 1888, condensed oxygen and nitrogen together with Professor Wróblewski. Obaliński was succeeded by Bronislaw Kader (1863–1937), a student of Mikulicz.

Chairs of Surgery were also being organized in other places. The Department of Surgery was founded in Vilnius in 1783, and in Warsaw in 1809; however both these centres existed only until the early 19th century.

In 1857 the Medical-Surgical Academy was established in Warsaw and in 1862 it became the Faculty of Medicine of the Warsaw Szkola Glowna. The most prominent Warsaw surgeons of the last century included Aleksander Le Brun (1803–1868), Polikarp Girsztoft (1827–1877), Hipolit Korzeniowski (1827–1879) and Julian Kosiński (1833–1914). A new surgical centre started flourishing in Poznań and the most famous surgeon of that time was Tomasz Drobnik (1858–1901).

When after World War I Poland regained independence, new horizons opened for the development of surgery. To the existing centres in Cracow, Warsaw and Lvov new ones were added in Vilnius where the University was re-opened and in Poznań following the establishment of a university there. In Vilnius surgery was headed by Professor Kornel Michejda (1887–1960) and in Poznań by Professor Antoni Jurasz (1882–1961), the author of the innovative method of pancreatic cystogastrostomy. The most famous Warsaw surgeons of that time were Antoni Leśniowski (1867–1939) and Zygmunt Radliński (1874–1941), and Hilary Schramm (1857–1940) and Tadeusz Ostrowski (1881–1941) in Lvov.

In Cracow Maksymilian Rutkowski (1867–1947) was appointed Professor of Surgery. He developed numerous surgical methods and encouraged expansion of various surgical specializations, e.g. orthopaedics, urology, neurosurgery, thoracic and cardiac surgery. Rutkowski was himself a pioneer of oesophageal surgery, developing oesophagectomy with replacement of the removed segment by the mobilized stomach drawn up through the chest using the Rutkowski, Lortat-Jacob method[5].

Further development of surgery in Poland ground to a halt with the outbreak of World War II. All the university schools were closed and the Professors sent to concentration camps. When open training of medical personnel was impossible in the occupied country, the Polish Faculty of Medicine was established at the University of Edinburgh with Professor Antoni Jurasz from Poznań as its Dean.

After World War II favourable conditions for academic surgery were created in the Polish People's Republic, first in the reopened universities and subsequently in ten Medical Academies functioning under the Ministry of Health. Pre-war Professors or their former students were appointed and they carried on the tradition established by the founders of the Polish School of Surgery and contributed much to the education of a vast number of surgeons, both general and representing various specialties such as orthopaedics, urology, neurosurgery, thoracic, paediatric, cardiac and vascular surgery.

Rydygier was the driving force behind the first Congress of Polish surgeons held in Cracow in October 1889. Surgeons from all the territories of the former kingdom of Poland participated, a constitution for the Society was drawn up and a membership register of over 200 created. Rydygier was elected the lifelong President of the Society and presided over the annual Congress held every year until World War I. Because Poland was partitioned between Russia, Prussia and Austria, the title Polish Association of Surgeons could not be adopted until 1921 at the first Congress held at Warsaw, now the capital of an independent Poland. At the 1921 Congress a resolution stressing the continuity of the Association with the previous Congress was unanimously approved. The Council of the Polish Association of Surgeons organized the VIII Congress of the International Society of Surgery in Warsaw in 1929. Since 1922 the Association has published the journal *Polski Przegląd Chirurgiczny*. During World War II the German occupation permitted no collective activities of the Polish Association of Surgeons.

The aims of the Association include the application of scientific progress in surgery, promotion of research in experimental and clinical surgery, cooperation in the organization of public health care and postgraduate education, and training of surgeons and representatives of Polish surgery at home and abroad.

National Congresses of the Polish Surgeons were held annually until 1952 and since then have been held every second year. Each has about 1000–1500 participants. The sections of the Society of Polish Surgeons organize, every second year, scientific conferences with participation of foreign guests, and the Society holds monthly scientific meetings. The Association is a member of the International Federation of Colleges of Surgeons.

The Centenary Congress of the Association will be held in Cracow in September 1989, a meeting which also celebrates the Bicentenary of the University Department of Surgery of the Jagiellonian University. The President of the Congress, Professor of Surgery in Cracow, is Professor Tadeusz Popiela.

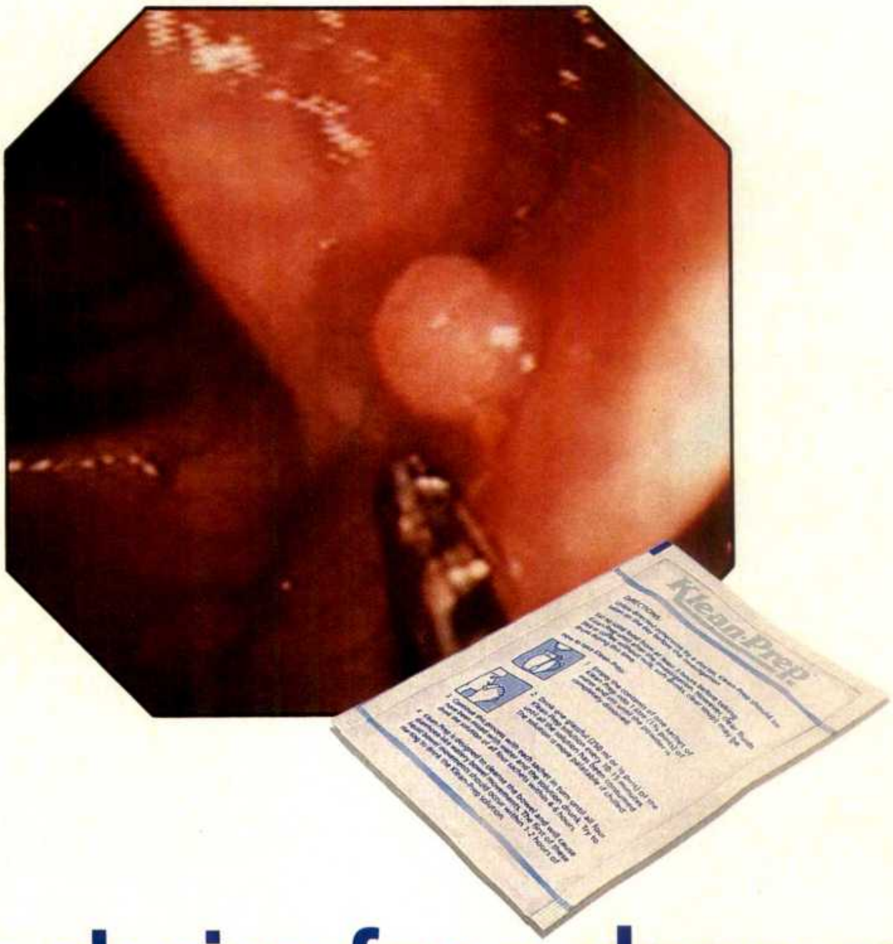
Klean·Prep*

Polyethylene glycol 3350, sodium sulphate, sodium bicarbonate, sodium chloride, potassium chloride



Today's choice for a clean colon

for colonoscopy, colonic surgery, barium enema

- **Bowel cleansing** Superior bowel cleansing to standard regimens (1,2).
- **Safety** Negligible water and electrolyte disturbance (3).
- **Well tolerated** (1,2,4) Pleasantly flavoured.
- **Economy** Shortens preoperative stay (1,2,4).

Abbreviated Prescribing Information: Presentation: An off-white powder, packed in 4 sachets. Each sachet contains: Polyethylene Glycol 3350 59.00g, Sodium Sulphate 5.685g, Sodium Bicarbonate 1.685g, Sodium Chloride 1.465g, Potassium Chloride 0.7425g. **Uses:** Bowel preparation before colonoscopy, colonic surgery, radiological examination and other related procedures. **Dosage and Administration:** Reconstituted solution for oral administration. *Adults (including the elderly):* The contents of one sachet to be dissolved in 1 litre of water. 250ml to be drunk rapidly every 10-15 minutes until all the solution has been consumed. The procedure to be repeated with all four sachets or until the rectal effluent is clear. The solution from all 4 sachets should be drunk within 4-6 hours. No dosage changes need be made for patients with renal insufficiency. If administered by nasogastric tube the rate of administration should be 20-30ml/minute. *Children:* Not recommended. **Contra-indications, Warnings etc.** *Contra-indications:* Gastro-intestinal obstruction or perforation, ileus, gastric retention, acute intestinal or gastric ulceration, toxic colitis or megacolon. Patients with body weight less than 20kg. *Warnings:* Extra care should be taken in patients with impaired gag reflex, reflux oesophagitis, those with diminished levels of consciousness and in ulcerative colitis. *Interactions:* All oral medications should be given at least 1 hour prior to administration. *Side-effects:* Nausea, abdominal fullness, bloating may be experienced. Abdominal cramps, vomiting and anal irritation occur less frequently. These effects normally subside rapidly. Urticaria and allergic reactions have been reported rarely. Should distension or pain arise the rate of administration may be slowed. *Use in Pregnancy:* Careful consideration should be given before use in pregnancy. **Precautions:** The reconstituted solution should be refrigerated and used within 24 hours. Any unused portion should be discarded. **Package quantity:** Unit dose pack of 4 sachets. **Basic NHS price:** £8.60. PL 5628/0003 Licence holder: Birex Pharmaceuticals Ltd. Further information is available from Norgine Limited. *Klean-Prep is a trademark.

Thoracic Surgery

Surgical Procedures on the Chest and Thoracic Cavity

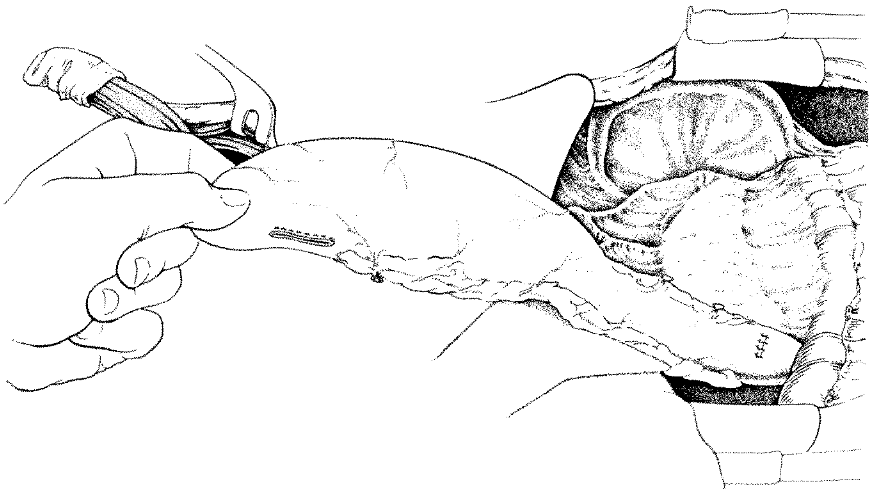
With a Foreword by D. B. Skinner

Translated from the German by T. C. Telger

Contributing Authors: U. Demmel, R. Grundmann, H. Hamelmann, H. Hofmann, T. Junginger, E. Kiffner, J. M. Müller, H. Pichlmaier, F. W. Schildberg, M. H. Schoenberg, M. Thermann, R. Thoma, M. M. Wanke, K. Zilles

1989. XII, 460 pp. 343 figs.
in 763 sep. illus., 15 anatomic color
plates. Hardcover DM 650,–
ISBN 3-540-18464-3

From the Foreword by Professor D. B. Skinner:
"... This volume is a major contribution to the world literature on thoracic surgery and marks the revitalization of an important school of non-cardiac thoracic surgery in Germany..."



Contents: Functional Operability in Thoracic Surgical Procedures. - Surgical Instruments, Materials, and Approaches. - Perioperative Management. - Surgical Treatment of Thoracic Trauma and Chest Wall. - Operations on the Breast. - Operations on the Lung and Tracheobronchial System. - Procedures on the Mediastinum. - Procedures on the Diaphragm. - Procedures on the Esophagus. - Topography of Surgically Important Regions. - Subject Index.

Thoracic surgery has undergone substantial change due to improvements in diagnosis and, subsequently, to more effective therapy. Starting with basic aspects of indications and pathophysiology, this book describes current surgical methods, including the operative conditions prerequisite for thoracic surgery. It demonstrates in detail to the surgeon the successive steps of surgical treatment in the thorax.
Of particular value is the supplementary section on anatomy where the plates can be folded out and thus continually consulted while reading. The work provides the surgeon starting out in the specialty with a concise presentation of well-tried operative techniques; it will facilitate decision-making and procedure in everyday practice and in cases of possible complications.

Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality. Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp–that's why they are World-Famous!

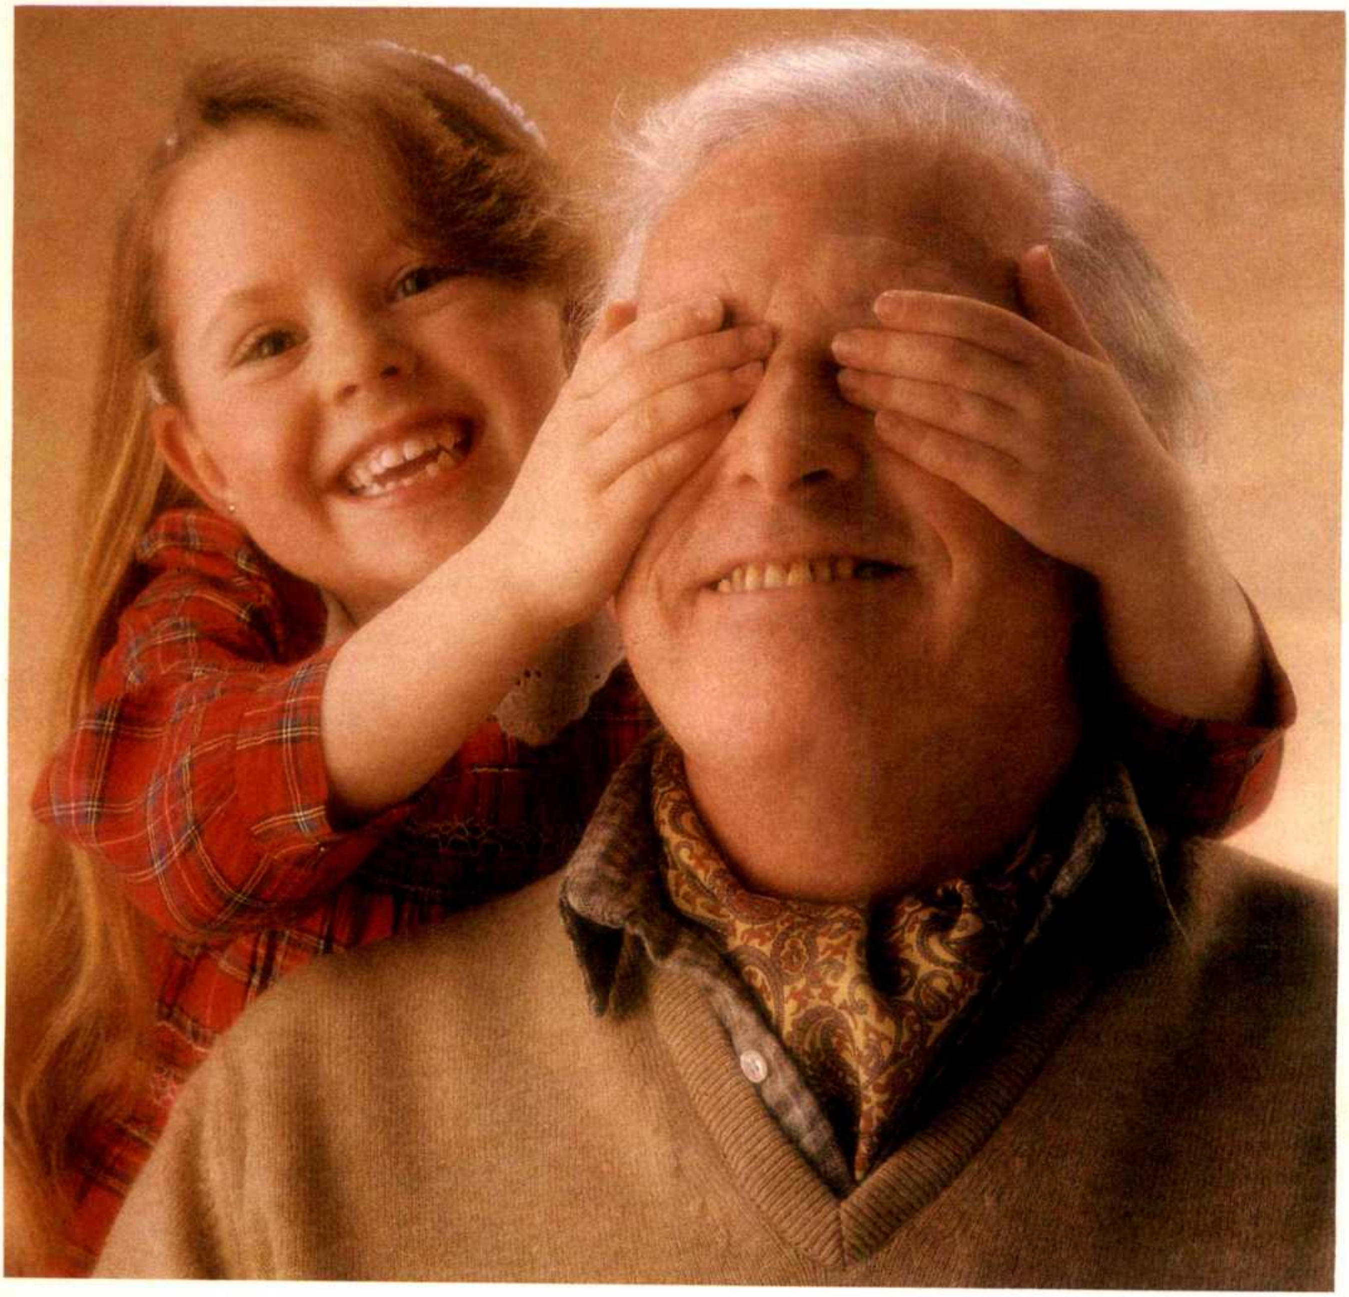
Guess which prostate cancer treatment most patients would choose.



In a recent study[1], 57 prostate cancer patients were invited to participate in choosing their treatment. All were informed that the two treatments available, sub-capsular orchidectomy or 'Zoladex', were similar in efficacy and side effects. 49 of the patients (86%) opted for 'Zoladex'.

A recent trial[2] has established the equivalence of 'Zoladex' to orchidectomy.

Zoladex

goserelin

Effective therapy without surgery.

▼ **'ZOLADEX' PRESCRIBING NOTES.**

Use: Prostate cancer suitable for hormonal manipulation. **Presentation:** A sterile depot containing goserelin 3.6mg. **Dosage and administration:** One depot injected subcutaneously into the anterior abdominal wall every 28 days. **Precautions:** Care with patients at particular risk of developing ureteric obstruction or spinal cord compression. Consider initial use of an anti-androgen at the start of therapy. **Side effects:** Hot flushes, decrease in libido and occasional breast swelling and tenderness. Skin rashes (generally mild). Occasional mild bruising at injection site. Initial transient increase in serum testosterone may cause temporary increase in bone pain. **Product licence number:** 29/0198. **Basic NHS Price:** £114.00 per depot. 'Zoladex' is a trademark. Further information is available from: ICI Pharmaceuticals (UK), Southbank, Alderley Park, Macclesfield, Cheshire SK10 4TF.

Perioperative anticoagulant control

It is a common clinical dilemma to balance safely the opposing risks of thromboembolism and haemorrhage in anticoagulated patients undergoing surgery. In the Hastings District, with a population of only 170000, two anticoagulated patients per month face surgery. A clear policy, kept under regular review, is therefore advisable but detailed advice on the anticoagulant control of such patients undergoing surgery is lacking.

It appears to be safe to discontinue anticoagulation for 6 days before and during non-cardiac surgery. No thromboembolic complications occurred after 180 operations on 159 patients with cardiac valve prostheses although 13 per cent experienced difficulties with haemostasis[1]. However, two patients with prosthetic mitral valves died from thromboemboli following a similar regimen[2], with four episodes of haemorrhage in another nine patients whose anticoagulants were continued. Some authors recommend replacing warfarin, whose mean(s d.) plasma half-life[3] is 37(15) h, with heparin until 6 h before the operation and restarting both after 36 h or less[4,5]. The use of postoperative heparin for those at highest risk is supported by evidence that intracardiac thrombi begin to form within hours of cardiac surgery[6]. Additional antiplatelet therapy reduces thromboemboli from prosthetic valves because platelet accretions may occur despite adequate anticoagulation. It is probably safe to continue warfarin during dental[4] or cataract[7] surgery, but opinion differs for regional anaesthesia[5] and central venous cannulation.

Guidelines should be simple but flexible. The aim is to achieve an international normalized ratio (INR)[8] of $<1{\cdot}5$ at the time of surgery, keeping the duration of subtherapeutic anticoagulation to a minimum and restoring full anticoagulation as soon as the risk of postoperative haemorrhage allows. Albumin binding and the resynthesis of coagulation proteins govern the rate at which normal coagulation is restored after stopping warfarin. This is 3–5 days as a rule but the metabolism of warfarin varies so that individual requirements must still be tailored to the INR and type of surgery. Vitamin K is best avoided because of difficulty in regaining control after its administration, although low-dose regimens (2·5 mg oral phytomenadione for 2 days before surgery[3]) have been advocated while continuing warfarin. For surgical emergencies in any anticoagulated patient, fresh frozen plasma should be used to reduce the INR to $<1{\cdot}5$.

Anticoagulated patients can be broadly divided into those with mechanical prosthetic valves and those receiving warfarin for any other reasons, such as venous thrombosis, pulmonary embolus or ventricular aneurysm. Elective procedures in the latter group should be delayed if possible until anticoagulant therapy has been completed. Patients should understand the increased risks of surgery and it may be helpful to compare these risks with those of spontaneous haemorrhage (1 per cent per patient-year[9]) or thromboemboli (3 per cent per patient-year[9]) for those with mitral prostheses who never have another operation.

Patients with prosthetic valves should be admitted on the day that warfarin is to be stopped, 3 days before surgery. The INR should be checked on admission. That evening, 24 h after the last dose of warfarin, intravenous heparin (initially 15000 units/12 h) should be started. The activated partial thromboplastin time should be checked 12 h later, aiming for 70–100 s. Heparin should be stopped 6 h before operation, and both the INR and activated partial thromboplastin time should be checked 1 h before surgery; consequently the operation is best scheduled last on a morning list or first in the afternoon. Surgery should be delayed or fresh frozen plasma used if the INR is $>1{\cdot}5$. The small but inevitable risks associated with any blood products warrant consideration in these circumstances. After the operation warfarin should be restarted as soon as the patient is taking oral fluids. Postoperative heparin is not required for patients with mechanical aortic valves unless the patient cannot drink for more than 48 h.

For those with mechanical mitral valves, two modifications are recommended because the risk of emboli is higher than with aortic prostheses. When warfarin is

---

Helpful discussions with surgical colleagues, Dr D A. Chamberlain and Dr R P H Thompson, were appreciated.

0007-1323/89/1107-02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

discontinued, 75 mg aspirin or 300 mg dipyridamole should be given daily. Six to 12 hours after the operation the heparin infusion should be restarted and continued until warfarin control is re-established. For short operations (less than 20 min) it may be preferable simply to use fresh frozen plasma, bearing in mind the associated risks.

Patients on anticoagulants for any reason other than for mechanical cardiac valves can have surgery after omitting three doses of warfarin. Routine admission the day before surgery is reasonable if appropriate instructions on omitting warfarin are included in the admission letter. The INR should be checked on admission and again before the operation. The preoperative dose of warfarin can be restarted with oral fluids. Where the risk of thromboembolism is considered particularly high (such as in patients with recurrent pulmonary emboli undergoing pelvic surgery), or when a delay of more than 48 h is anticipated before warfarin can be restarted, a postoperative heparin infusion would be appropriate.

Three days without warfarin, intravenous heparin for selected patients, antiplatelet therapy with mitral prostheses and a written policy form the basis of management. These practical guidelines need to be tailored to individual patients but may help junior staff who often have responsibility for anticoagulant control and also form the basis for discussion on this neglected subject.

Restorative proctocolectomy is the first choice elective surgical treatment for ulcerative colitis

Proctocolectomy and an end ileostomy have remained the cornerstone of surgical treatment for ulcerative colitis throughout the last 50 years. Many patients owe their lives to this procedure. It eradicates the disease and restores the patient's well-being. All general surgeons are trained in its execution, and most understand its complications. It has stood the test of time, and recently has quite rightly been the preferred option when treating young patients with colitis. The price paid for cure, however, is high; an ileostomy may cause mechanical, psychosocial and sexual problems, the latter occurring despite an intersphincteric dissection of the rectum[1]. It is not surprising, therefore, that surgeons have striven to improve the quality of their patients' lives but until recently, their attempts to do so were far from satisfactory. Subtotal colectomy and ileorectal anastomosis was always regarded with scepticism, not least because of the high risk of carcinoma development[2]. Transformation of the end ileostomy to a continent Koch ileostomy has never become popular because it has a high failure rate[3].

Attempts to eradicate the disease yet restore gastrointestinal continuity and continence were for a long time regarded as laudable but conflicting objectives. It is therefore perhaps not surprising that the first report of mucosal proctectomy and ileoanal anastomosis in 1948 was received with surprise and perhaps a certain degree of incredulity. Ravitch[4] claimed that he could eradicate the disease by colectomy and rectal mucosectomy and achieve gastrointestinal continuity and continence by drawing the ileum down through the denuded rectal cuff and anastomosing it to the anal canal. The scepticism about his initial work was fuelled by other surgeons who were unable to reproduce his results. We had to wait 30 years until Martin and his colleagues in Cincinnati, using a modification of Ravitch's original operation, showed that mucosal proctectomy and ileoanal anastomosis was indeed feasible[5]. However, it rapidly became obvious that the operation had an Achilles' heel, namely frequency and urgency of defaecation. It was then that Sir Alan Parks, applying Koch's concept, created an ileal pelvic reservoir so as to increase the capacity of the neorectum[6]. This simple yet effective innovation considerably reduced the frequency of defaecation and converted the procedure from a merely feasible one into a practical alternative to proctocolectomy. Parks' first paper on the subject was in 1978, but 10 years later proctocolectomy still remains the procedure of first choice in most hospitals in the UK. Surgeons quite rightly tend to be conservative with a small 'c'; before an operation is accepted by the *corps chirurgie* it has to be shown to have stood the test of time. Is 10 years therefore a sufficient period to have elapsed for restorative proctocolectomy to have reached the status of the first choice elective procedure for most patients with ulcerative colitis?

There is no doubt that the last 10 years have seen considerable modifications to Parks' original operation. The procedure used to be tedious and technically demanding, the mucosectomy being mainly responsible for the difficulties. At first it was thought necessary to denude 10–12 cm of rectum, but gradually it was realized that the rectal cuff could be much shorter, no more than 4–5 cm. Not only did this simplify the procedure, but the modification reduced the incidence of cuff abscess and pelvic sepsis. Initially, Parks constructed a triplicated pouch with a long efferent spout, 5 cm in length. Half of his patients, however, failed to evacuate spontaneously; the elimination of the efferent spout virtually eradicated the problem. Configuration of the pouch has also undergone experimentation, the triplicated design being joined by the J (Reference 7) and more recently the W designs[8]. While the debate continues about the best design of pouch, all the data show that the greater the pouch volume the better the result in terms of frequency and urgency.

Several large series have now been published which, having incorporated some of the modifications discussed above, demonstrate the effectiveness of the procedure[9]. Thus most patients undergoing the procedure can now expect to be continent most of the time, have a frequency of about 6 bowel actions per 24 hr 6 months after ileostomy closure, delay defaecation for 30 min and retain normal bladder and sexual function. It is true that the operation has defects; many patients have to evacuate once during the night, some leak faeces occasionally and others have attacks

0007-1323/89/1109-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

of pouchitis which is akin to their previous colitis. Most patients, however, are very prepared to put up with these imperfections to avoid an ileostomy. If at the end of the day the disadvantages outweigh the benefits, an end ileostomy can still be constructed. It might be expected, therefore, that such an outlook would establish the operation as the first choice procedure. This has not yet occurred, probably because most surgeons still regard the operation as technically demanding, despite the modifications. The ground, however, has now shifted with the introduction of circular stapling instruments which have considerably simplified the procedure. Several techniques have recently been described[10–12]; and despite differences they are similar in principle. Thus, the rectum is dissected right down to the pelvic floor and cross-stapled using an appropriate transverse stapling instrument. A pouch is constructed either by hand or by a GIA® stapler (US Surgical Corporation and Auto Suture UK, Ascot, UK). The pouch–anal anastomosis is achieved by one of the circular stapling guns after first detaching the head and inserting the shaft through the wall of the closed anorectal stump. The new Premium CEEA® stapler (US Surgical Corporation and Auto Suture UK) is particularly useful in this regard. These techniques eliminate the need for a mucosectomy, shorten the procedure by about one hour and probably ensure a more secure anastomosis. They are also thought to inflict less damage on the anal sphincter than the conventional technique, although this is controversial[12]. Despite this considerable technical advance, there remains one problem: diseased rectal mucosa is left behind. However, provided the rectal dissection is taken right down to the pelvic floor, no more than 2–3 cm of residual anorectum above the dentate line should remain. The subsequent risk of neoplastic change must be very small, and surveillance of the region should be relatively easy. Even so, in the well-built male patient with a narrow pelvis in whom it may not be possible to dissect the rectum down to the pelvic floor, the conventional restorative proctocolectomy is probably more appropriate.

During the last 40 years, we have seen the operation of restorative proctocolectomy evolve from the experimental technique of Ravitch through the practical yet technically demanding procedure described by Parks to the relatively easily performed stapled pouch–anal anastomosis. The latter has taken the procedure from the specialized centres and placed it firmly in the ambit of most general surgeons with an interest in coloproctology. Many will argue, correctly in my view, that before embarking on the stapling procedure the surgeon should be trained in endoanal techniques in case he has to redeem a difficult situation. Since most surgeons with colorectal expertise possess these skills, there is little doubt that restorative proctocolectomy will and should be offered as the first choice elective operation to most young patients with ulcerative colitis who require surgical treatment.

Primary disorders of oesophageal motility

R. C. Stuart and
T. P. J. Hennessy

Department of Surgery, St James's Hospital, Dublin 8, Ireland
Correspondence to:
Professor T. P. J. Hennessy

Primary motor disorders of the oesophagus have distinct manometric patterns but require full oesophageal investigation to exclude a secondary cause. Myotomy and forceful dilatation give good results in achalasia, though myotomy is superior in the long term. Indications for surgery are rare in diffuse spasm and nutcracker oesophagus. Non-cardiac chest pain may be related to reflux, diffuse spasm or nutcracker oesophagus, but correlation between motor abnormalities and symptoms is poor and psychological disturbances are frequent.

Keywords: Motility, oesophagus, achalasia, diffuse spasm, nutcracker oesophagus, gastro-oesophageal reflux, cricopharyngeus, manometry

Oesophageal motility disorders include a wide range of recognizable clinical entities and a variety of conditions in which the motor dysfunction cannot easily be classified. They may involve separately the upper oesophageal sphincter, the oesophageal body, or the lower oesophageal sphincter, but more than one region may be affected. Motor disorders are classified as primary when no underlying oesophageal or systemic disease influencing motility is present, or secondary when there is an identifiable oesophageal or systemic disorder. Manometric studies provide the objective evidence with which a clinical diagnosis can be confirmed, but radiographic, endoscopic and radionuclide investigation may also provide useful clinical information.

Upper oesophageal sphincter disorders

The high-pressure zone of the upper oesophageal sphincter corresponds closely to the anatomical position of the cricopharyngeus muscle. Manometrically it is 2–4 cm long and thus exceeds the anatomical length of the cricopharyngeus[1,2]. It is generally accepted that a portion of the inferior constrictor and possibly the upper oesophageal circular smooth muscle fibres contribute to the sphincter[3,4], although it is possible that the longer length on manometry may be artefactual[5]. One major problem limiting the usefulness of manometry in studying the upper sphincter is its axial asymmetry Failure to appreciate this makes many of the older studies of upper sphincter dysfunction of doubtful validity. Recently, modifications of sleeve sensors have been used successfully to record upper oesophageal sphincter function[6] These studies[6] demonstrate that the muscle is normally in a state of tonic contraction with a mean(s.d.) pressure of 40(17) mmHg There is little temporal variation in a given subject, and a range of 20–70 mmHg between subjects. The pressure increases towards the end of inspiration to exclude air from the oesophagus. The sphincter pressure falls to <10 mmHg during deep sleep, and relaxes when a bolus is propelled by the pharyngeal constrictor muscles towards the oesophagus, during vomiting and while belching[6,7] Slow or focal distension, particularly in the proximal oesophagus, favours reflex upper oesophageal sphincter contraction[8]. Unlike the lower oesophageal sphincter there are no significant changes in upper sphincter pressure postprandially or during episodes of spontaneous gastro-oesophageal reflux[6]. In humans the nerve supply of the upper oesophageal sphincter is parasympathetic from the vagi, probably via the pharyngeal plexus The reflex responses to oesophageal stimuli are probably mediated by thoracic and cervical vagal afferents. Cervical vagal cooling in the dog blocks upper oesophageal sphincter contractile response elicited by oesophageal distension with fluid[9]. Efferent nerves to the upper sphincter have their cell bodies in both the dorsal motor nucleus and nucleus ambiguous of the medulla[10].

There are many disorders that affect the swallowing process, but there are few primary motor disorders of the upper oesophageal sphincter Primary motor disorders of upper sphincter function include both abnormalities of the resting tone and abnormalities of cricopharyngeal relaxation and opening.

In its normal contracted state the sphincter can be recognized radiologically as a posterior indentation at the pharyngo-oesophageal junction[11] Seaman, however, regarded this posterior bar as evidence of abnormal muscular spasm[12] Upper oesophageal spasm may occur as an isolated phenomenon and may give rise to the globus syndrome, in which there is a sensation of something sticking in the pharynx although no food has been ingested[13]. In such patients resting sphincter pressures of 140–200 mmHg have been recorded in contrast to pressures of 70–140 mmHg in corresponding normal subjects[13]. Diagnostic criteria remain to be identified for primary cricopharyngeal spasm. Hunt *et al.* reported higher than normal upper sphincter pressures in patients with reflux oesophagitis[14] and Belsey noted an improvement in these patients' symptoms after antireflux surgery[15]. This association between gastro-oesophageal reflux and cricopharyngeal spasm is controversial, but emphasizes the need to rule out reflux before a diagnosis of primary upper sphincter spasm can be made. Experimentally, Freiman *et al.* demonstrated an increase in upper sphincter pressure in response to intraoesophageal acid in a canine model[9] The maximum response to acid occurred on perfusion at the sphincter and the response was less as acid was perfused more distally. Clinically, Gerhardt *et al.* demonstrated a similar response to acid perfusion in humans[8]. However, Kahrilas *et al* studied the effect of spontaneous gastro-oesophageal reflux on upper sphincter pressure and were unable to detect any change in pressure using a superior manometric technique which employed a sleeve sensor[6]. In patients with pathological gastro-oesophageal reflux reports are also conflicting[14,16].

Primary abnormalities of cricopharyngeal relaxation and opening involve either incomplete relaxation or premature closing of the sphincter. Although incomplete relaxation of the upper sphincter can be secondary to underlying diseases such as polio, recurrent laryngeal nerve and bulbar paralysis, and thyrotoxic myopathy, and may occur after partial pharyngectomy, in the majority of instances there is no obvious underlying cause. The term achalasia of the cricopharyngeus

0007-1323/89/1111-10$3 00 © 1989 Butterworth & Co (Publishers) Ltd

muscle has been used to describe incomplete relaxation of the sphincter[17]. The diagnosis is suggested by the patient's history and by observing his attempt to drink, and is confirmed by cineradiography[18]. Hypopharyngoscopy and oesophagoscopy are required to exclude other disease. Studies of the pressure dynamics within the pharynx have diagnostic value, although this is not required for diagnosis[19]. Treatment of achalasia, whether primary or secondary, calls for cricopharyngeal myotomy. The results are excellent in most patients[19]. If necessary the sphincterotomy can be performed under local anaesthesia[19]. Bougienage of the cricopharyngeus is of little value, except in children[20].

Premature closing of the cricopharyngeus has been associated with Zenker's diverticulum. Although patients with a pharyngeal pouch frequently exhibit a radiological posterior bar, manometric studies demonstrate normal tonic contraction of the upper sphincter and normal relaxation during swallowing[21] In the patients studied by Ellis *et al.*, sphincter pressures were lower than in control subjects and relaxation was complete[21]. However, contraction of the cricopharyngeus was resumed before the completion of swallowing[21]. Similar findings were reported by Lichter[22], and Duranceau *et al.*[23] found a temporal incoordination in four of ten patients. Cricopharyngeal myotomy extending distally into the upper oesophagus and combined with diverticulopexy gives excellent results in patients with a pharyngeal pouch. Alternatives to cricopharyngeal myotomy and diverticulopexy or diverticulectomy are associated with higher recurrence rates. Dohlman and Mattsson have advocated peroral endoscopic diathermy division of the wall between the diverticulum and the oesophagus, but experienced a recurrence rate of 7 per cent[24].

Achalasia

Achalasia of the oesophagus is the most well defined motility disorder encountered by the surgeon The incidence of achalasia is approximately one in 100 000 per year[25], and there is a regional variation in the prevalence which was 13·4 in 100 000 over a 10-year period in Ireland in contrast to 7·1 in Wales, 10·8 in England and 11·2 in Scotland[26] The clinical symptoms of dysphagia, regurgitation and pain may suggest the diagnosis, and the radiological features may be characteristic but manometric studies remain the most reliable means of establishing a diagnosis Infiltration of the lower oesophageal myenteric plexus by a tumour of the cardia can closely resemble achalasia, and is termed pseudoachalasia It is necessary to perform endoscopy in patients with achalasia[27–29] to exclude this possibility. Achalasia is characterized by absence of peristalsis in the smooth muscle of the oesophageal body, incomplete relaxation of the lower oesophageal sphincter in response to swallowing, and a normal or high resting lower oesophageal sphincter pressure. The resting pressure in the oesophagus is higher than normal, possibly owing to stasis of food, fluid and air. This elevation is accentuated during eating[30] and may reach 120 mmHg (authors' observation) A small number of patients exhibit vigorous achalasia, a variation in which non-peristaltic contractions of more normal amplitude are seen[31,32].

Although the cause of achalasia is unknown it is hoped that the recent advances in the understanding of the physiology of the lower oesophagus will provide the answer. The intramural nerve plexus receives preganglionic innervation either directly from the vagus or indirectly via interneurones, and the postganglionic neurones from these plexuses have both excitatory and inhibitory components to the lower oesophageal sphincter. The mediator of the inhibitory neurones is neither adrenergic nor cholinergic, and the excitatory mediator is cholinergic[33]. The inhibitory mediator is probably vasoactive intestinal polypeptide, neuropeptide Y, enkephalin or substance P[34–36]. Both vasoactive intestinal polypeptide and neuropeptide Y coexist in oesophageal neurones and are the most abundant neurotransmitters in the lower oesophagus; they are therefore considered to be the most likely mediators in lower oesophageal sphincter relaxation[37,38]. In achalasia, incomplete or absent lower oesophageal sphincter relaxation in response to swallowing[39] and a paradoxical contractile response to cholecystokinin–octapeptide[40] indicate absent or functionally impaired postganglionic inhibitory neurones. Exaggerated responses to cholinomimetics also suggest denervation. A reduction in the number of ganglion cells in the myenteric plexus in the affected part of the oesophagus has been suggested in the past[41–43] Aggestrup *et al.*[44] have demonstrated a diminished vasoactive intestinal polypeptide nerve supply and a significantly reduced concentration of vasoactive intestinal polypeptide in the oesophageal smooth muscle of patients with achalasia. The most powerful neurotransmitter, identified with 400 times the ability of vasoactive intestinal polypeptide to induce lower oesophageal sphincter relaxation, is calcitonin gene-related peptide, and calcitonin gene-related peptide-immunoreactive nerves have been shown to innervate the lower oesophageal sphincter. Studies in achalasia patients are awaited[45] It is still uncertain, however, whether the degenerative changes in the intramural neurone in patients with achalasia are a consequence or a cause of the disease[41,46]. Recent observations argue against a general neuronal degeneration in achalasia, as the cholinergic innervation of the lower oesophageal sphincter in achalasia is either normal or only minimally impaired[47], and within the non-cholinergic non-adrenergic pathway substance P levels in the lower oesophagus are unaffected in achalasia[48].

These changes in the innervation of the oesophagus in achalasia relate to the postganglionic intramural plexuses. There is some inconclusive evidence that a more generalized neurological defect exists. Both structural and functional defects have been shown in the vagus of achalasia patients[41,49–51]. Degenerative changes in both myelinated and non-myelinated vagal nerve fibres are found in surgical resection specimens[41,52]. However, the degree of nerve fibre involvement is highly variable, and the significance of such changes in necropsy material and their relationship to the intramural ganglion cell loss is unclear. Reports that 30–50 per cent of patients with achalasia demonstrate abnormal gastric secretory response to insulin-induced hypoglycaemia have been used as evidence that abnormal vagal function is present in achalasia patients[53–55]. Others suggest that this is due to a reduction in parietal cell mass rather than vagal dysfunction, and have failed to confirm abnormal secretory patterns[54]. The functional status of the vagus nerve supplying both the alimentary tract and heart was completely normal in most of the 28 patients with achalasia studied by Atkinson *et al.*[56]. Abnormalities in the dorsal motor nucleus in humans with achalasia have been reported by Kimura[51], and stereotaxic ablation of the dorsal motor nucleus has produced an achalasia-like disturbance in oesophageal function in both canine and feline models[57].

Apart from the neurological abnormalities present, changes in the smooth muscle itself have been demonstrated[41,52,58,59] The abnormalities are variable and non-specific, and suggest denervation atrophy rather than a primary muscular defect However, it is not clear whether previous forceful dilatation could produce similar changes. At the level of the neuromuscular junction and effector organ the mechanism of lower oesophageal sphincter relaxation involves the cyclic nucleotides cAMP and cGMP with their respective cyclic nucleotide-dependent protein kinases[60,61] Vasoactive intestinal polypeptide and isoproterenol both produce lower oesophageal sphincter relaxation associated with an increase in cAMP content and an activation of cAMP-dependent protein kinase in the opossum[60,61]. These pathways remain to be studied in the oesophageal smooth muscle from patients with achalasia.

In summary, the site or cause of the disorder in achalasia is yet to be determined. Currently available knowledge suggests that further evidence of a selective denervation phenomenon involving the non-cholinergic non-adrenergic inhibitory nerves, which have as their neurotransmitters vasoactive intestinal polypeptide and neuropeptide Y, should be sought. A generalized neurological disorder or smooth muscle defect is unlikely to be present The underlying cause of such denervation is not understood and may be toxic, infectious, degenerative or metabolic in origin.

The treatment of achalasia consists of forceful dilatation or myotomy. There is no convincing evidence that pharmacological therapy has a significant role in management, particularly as dilatation or myotomy produces good or excellent results in 90 per cent of patients. Many reports of successful pharmacological manipulation of the lower oesophageal sphincter and oesophageal body in achalasia have appeared in recent years. Satisfactory response to terbutaline sulphate (a β-adrenergic agonist)[62], aminophylline[62], isosorbide dinitrate[62–65] and nifedipine[64,66–69] has been reported. None of these claims is based on sufficient numbers of patients in prospective or placebo-controlled trials. The only role of these agents at present would seem to be as an adjunct to partially successful dilatation or surgery, or when age or medical status of the patient prevents adequate dilatation or surgery.

It is impossible to state definitively whether forceful dilatation or surgical myotomy is superior in the management of achalasia. Only one prospective randomized trial has been undertaken. Csendes *et al.*[70] reported good or excellent results in all 20 patients treated surgically in contrast to only 12 of 18 (67 per cent) patients treated by dilatation. The mean follow-up was short (3·5 years), the numbers studied small, and the technique of dilatation has been criticized on the grounds of its very short duration (two dilatations of 3–5 s) and the use of atropine, which may relax the sphincter and thus render the stretch less effective.

Collective reviews of retrospective unrandomized reports of results of surgical and forced dilatation yield results similar to those of Csendes' prospective randomized study[70]. In a review of forceful dilatation therapy for achalasia conducted by Vantrappen and Janssens[71] good or excellent results were reported in 71·8 per cent (range 61–94·5 per cent)[72,73] of a total of 1371 patients. Andreollo and Earlam[74] reported excellent or good results following Heller's operation in 89 per cent (range 65·5–100 per cent)[75–78] of 5002 patients in a literature review extending from 1970–1985. Patients who have failed to benefit from forceful dilatation appear to respond well to myotomy.

Both dilatation and myotomy are relatively safe procedures. The overall mortality for Heller's myotomy is 0·2 per cent[74], with slightly higher mortality rates occurring in small series of patients[79–81]. The mortality rate following forceful dilatation in the Mayo clinic series was 0·46 per cent and in the Leuven series was 0·24 per cent[82,83]. Oesophageal leak following myotomy and perforation following forceful dilatation are the most serious causes of early morbidity Overall, oesophageal fistula and empyema occurs in 0·4 per cent of myotomy patients[74], while the incidence of perforation following forceful dilatation is in the region of 2·3 per cent, ranging from 1·1 to 4·9 per cent[84–86]. Vantrappen *et al* [87] report impressive results in managing these perforations conservatively, though most would advocate early surgical repair particularly in view of the element of distal obstruction due to the defective lower sphincter[84,88] The most troublesome late complication following therapy is reflux oesophagitis leading to the formation of late stricture. This is more common following myotomy than forceful dilatation. The true incidence of reflux oesophagitis after myotomy is not clear; Ellis *et al.*[89] and Okike *et al.*[82] report a 3 per cent incidence of clinically significant reflux oesophagitis. Other reports claim a 20–50 per cent incidence of gastro-oesophageal reflux after myotomy[75,90–92].

Such diverse reports reflect the various methods employed in assessing gastro-oesophageal reflux and the significance attached to reflux when detected. The overall incidence in Andreollo and Earlam's review was (mean(s.d)) 8·6(7·0) per cent[74]. Vantrappen and Hellemans[83], in a review of 1045 cases collected from 16 published papers on achalasia treated with pneumatic dilatation, found a 10 per cent incidence of reflux oesophagitis. The incidence of peptic stricture accurately reflects the significance of gastro-oesophageal reflux following treatment. Results from the Mayo clinic from Ellis[93], and Okike[82], show a 3 per cent incidence of peptic stricture following myotomy. Vantrappen reported a 0·7 per cent personal incidence of peptic stricture following pneumatic dilatation[71], and found a 3·4 per cent incidence in a literature review[83].

It may be reasonable to accept forceful dilatation as the initial treatment, particularly in patients over 45 years of age, with a history of >5 years and with a moderately distended oesophagus[71,94]. Dilatation should not be performed more than twice, particularly in young patients. Patients who do not respond to two dilatations are unlikely to benefit from further dilatations. The risk of perforation increases as the number of dilatations increases. Multiple dilatations make the operation of myotomy technically more difficult owing to obliteration of tissue planes and fibrous adhesions. Future reports on forceful dilatation should take account of the variety of dilators and techniques employed in order to be clinically useful. Assessment of balloon size, single *versus* multiple dilatations and duration of distension are also needed.

When performing oesophageal myotomy for achalasia we prefer a left thoracotomy approach, extending the myotomy from the inferior pulmonary vein to the gastro-oesophageal junction[95]. It is important to avoid extending the myotomy on to the anterior gastric wall. Extension of the myotomy to only 0·5 cm distal to the gastro-oesophageal junction is adequate to relieve symptoms but will still prevent gastro-oesophageal reflux. This epithelial junction can be seen when the mucosa has been mobilized and is the only accurate way of limiting the distal incision. Intraoperative manometry as an adjunct to surgery has been suggested by Hill *et al.*[96]. The incidence of gastro-oesophageal reflux following this approach is 7·7 per cent. Addition of an antireflux procedure results in a 7·3 per cent incidence of gastro-oesophageal reflux, a difference which is not significant[74]. On the other hand if a transabdominal approach is used when performing the myotomy the incidence of gastro-oesophageal reflux is 13·2 per cent. The incidence is reduced to 7·4 per cent by adding an antireflux procedure[74] and this may be the only indication for the combination of myotomy and an antireflux procedure

When symptoms recur owing to incomplete myotomy or healing of the myotomy incision, good results can be obtained by remyotomy[97–100]. Resection is indicated when recurrent symptoms occur in the presence of gross dilatation[99]. Demos[100], on the other hand, recommends performing a Y–V cardioplasty in patients with true megaoesophagus with areas of kinking. In addition he recommends a cardioplasty when recurrent symptomatic achalasia has occurred in the presence of an apparently complete myotomy.

There is a sevenfold increased incidence of squamous cell carcinoma of the oesophagus in patients with long-standing untreated achalasia. Harley[101] reviewed 3679 cases of achalasia and found an incidence of carcinoma of the oesophagus in achalasia patients of 3·3 per cent with a range of 0·3–20 per cent This incidence may not change even after seemingly successful surgical management[102]. The cause of this is unknown but may be due to the chronic retention of oesophageal content which has been shown to have a pH between 4 and 5·5 and a high lactic acid content[103]. These tumours may arise anywhere in the oesophagus and, because of the confusion caused by the symptoms of achalasia may remain undiagnosed until late, with a consequently worsened prognosis

Diffuse oesophageal spasm

Diffuse oesophageal spasm is a rare disorder of oesophageal motility. Unfortunately, the classification of those motility disorders previously referred to as oesophageal spasm has evolved in an ill-defined manner, and today many of the patients previously felt to have had diffuse oesophageal spasm would certainly be reclassified. This makes interpretation of published reports difficult. The one diagnostic group to emerge clearly from the confusion consists of patients with nutcracker oesophagus.

Characteristically, patients with diffuse oesophageal spasm present with central chest pain and/or dysphagia[104]. The pain may have many features in common with angina pectoris associated with myocardial ischaemia[105]. Often the patients are referred to the gastroenterologist or surgeon by a cardiologist after full investigation has failed to reveal underlying obstructive coronary artery disease. The initial symptom response often seen with nitroglycerine is probably caused by the smooth muscle relaxant effect of the drug on the oesophageal muscle[106–108].

The diagnosis of diffuse oesophageal spasm is based on manometric findings of simultaneous contractions in response to wet swallows in the presence of normal lower oesophageal sphincter function[109–111]. These simultaneous contractions are not present in all swallows, but should be present in ≥30 per cent. Usually the contractions are multi-peaked (≥3 peaks), and prolonged (≥7·5 s). The amplitude of these waves is not of diagnostic significance, and may be low, normal or high[99,102]. When the waves are almost all simultaneous it may be difficult to differentiate between diffuse oesophageal spasm and vigorous achalasia in which the wave amplitude is relatively normal[32]. The inability of the sphincter to relax in the latter is the main differentiating feature. There are anecdotal reports of intermediate forms of dysmotility However, many are poorly documented without full details of investigations. Other investigations of oesophageal function will usually help to establish the true diagnosis. This is particularly true of the barium swallow In diffuse oesophageal spasm the appearance may vary from a mild serration of the margins of the barium-filled oesophagus (tertiary contractions) to subdivision or outpouching of the oesophageal outline. The striking radiographic findings that may be associated with this condition have prompted the use of colourful synonyms, including curling, beading, corkscrew oesophagus, rosary bead oesophagus, functional diverticula, pseudodiverticulosis, segmental spasm, elevator oesophagus and knuckle-buster[112]. These features are very non-specific and are frequently seen in elderly patients with presbyoesophagus[113,114]. The barium swallow is of use only as an adjunct to establish the diagnosis when difficulty is experienced in distinguishing between diffuse oesophageal spasm and achalasia

To increase diagnostic accuracy, a number of provocation tests have been suggested. The cholinergic agents metacholine, bethanechol, carbachol, the cholinesterase inhibitor edrophonium chloride, along with pentagastrin and ergonovine maleate have all been used[115–121]. In the absence of a complete cardiac evaluation it is unwise to use ergonovine. Edrophonium is without this risk and is the most widely employed provocation test agent. A negative response does not exclude the disease Typical manometric features may be provoked in the absence of symptoms, and symptoms may also be provoked in patients with achalasia and nutcracker oesophagus. The diagnostic value of provocation tests is, therefore, somewhat limited

There is no consensus of opinion regarding the relationship between the manometric findings of diffuse oesophageal spasm and the symptoms that the patient experiences A patient with periodic chest pain and/or dysphagia will exhibit manometric abnormalities while asymptomatic, and even when symptoms are reproduced using provocation tests such as ergometrine there is no correlation between the symptoms and worsening of the manometric findings[115,119,122,123]. Furthermore, completely asymptomatic elderly volunteers exhibit features typical of diffuse oesophageal spasm on manometry[113,114]. Other studies of oesophageal function do not correlate with the degree of abnormality demonstrated on manometry in patients with diffuse oesophageal spasm Clouse and Lustman demonstrated an association between diffuse oesophageal spasm and psychiatric illness such as depression and anxiety[124].

For diffuse oesophageal spasm to be considered a primary disorder of oesophageal motility a complete investigation of the oesophagus must be undertaken to exclude coexisting disorders. Manometric criteria alone are insufficient to establish the diagnosis.

Diffuse oesophageal spasm cannot, therefore, be diagnosed when there is coexisting gastro-oesophageal reflux; an organic lesion of the oesophagus such as carcinoma, stricture, web or diverticulum; previous oesophageal surgery such as vagotomy or antireflux surgery; and systemic disorders known to influence oesophageal motility such as diabetes mellitus, chronic alcohol abuse and scleroderma. Similar reservations apply to nutcracker oesophagus Before making a diagnosis of diffuse oesophageal spasm on the basis of manometric criteria all patients should undergo upper gastrointestinal endoscopy and 24-h ambulatory pH monitoring to demonstrate that coexisting pathology is not present.

McCallum described a clinical, radiological and manometric syndrome identical to diffuse oesophageal spasm and secondary to gastro-oesophageal reflux[125]. Little *et al.* described the production of simultaneous repetitive contractions in the oesophageal body in a feline model of incomplete obstruction of the lower oesophagus[126]. Similar findings were present in patients with benign peptic oesophageal strictures and patients with excessively tight antireflux surgery. Indeed, this response of the oesophageal body to distal obstruction has previously been suggested to be relevant in diffuse oesophageal spasm, and some cases of diffuse oesophageal spasm with incomplete relaxation of the lower oesophageal sphincter have been reported[127]. The facts that the great majority of patients with diffuse oesophageal spasm have normal lower oesophageal sphincter relaxation and that oesophageal transit time is normal in many cases of diffuse oesophageal spasm[127,128] argue against this being caused by abnormal lower oesophageal sphincter function. This further emphasizes the need for full investigation of the oesophagus and the need for awareness of the underlying disorders which can cause abnormal motor patterns that mimic diffuse oesophageal spasm.

Although the underlying cause of diffuse oesophageal spasm is unknown there is some evidence that the abnormal contractions could result from a neuropathic disorder. The possibility of a common pathophysiological mechanism between diffuse oesophageal spasm and achalasia has been entertained[129]. The main feature in common is the exaggerated response to cholinomimetics, suggesting a denervation phenomenon[116,130]. The controversy surrounding the finding of incomplete lower oesophageal sphincter relaxation in a proportion of patients with diffuse oesophageal spasm has also been used as evidence for a common aetiology with achalasia[116]. It is unlikely, however, that a distinct lesion primarily involving the lower oesophageal sphincter could be operative, and a more diffuse lesion seems probable since abnormal contraction waves are always observed, yet failed lower oesophageal sphincter relaxation is noted in few cases. Recent electromyographic studies have demonstrated spike-independent contractions of the oesophageal body in patients with diffuse oesophageal spasm[131]. These findings may represent impaired inhibitory neural mechanisms. Heightened excitability of spontaneous spike activity has also been reported in patients with diffuse oesophageal spasm, an observation similarly made in patients with achalasia. This finding was also considered to represent impaired non-cholinergic, non-adrenergic inhibitory neurones[132]. An imbalance between excitatory and inhibitory innervation could conceivably lead to simultaneous and repetitive contractions, possibly of increased amplitude[133]. Despite these data suggesting functional derangements of the neural control of muscle contraction in patients with diffuse oesophageal spasm, there is little documentation of a neuropathological lesion. Disrupted vagal fibres within the oesophageal wall have been noted by electron microscopy in a small group of patients with diffuse oesophageal spasm[134]. Whether this finding applies to all patients with similar manometric findings is unclear. The only finding present in the majority of patients with diffuse oesophageal spasm is hypertrophy of the smooth muscle in the oesophageal wall, which can be demonstrated on barium swallow[135], computed tomography[136] or at the time of operation[137,138].

Because of the diagnostic confusion, the poorly understood pathophysiology, the inability to link symptoms to manometric abnormality, and the association with psychiatric disorders, the treatment of diffuse oesophageal spasm remains uncertain. A detailed history is necessary to establish symptom frequency and severity. Any precipitating cause should be eliminated as far as possible. Some patients respond to reassurance that the pain is not of cardiac but of oesophageal origin, that it will not progress and is not life-threatening. Short-acting and long-acting nitrate preparations[27–29,139] as well as hydralazine[140] have, in uncontrolled trials, relieved symptoms and improved manometric or radiographic findings in some patients. When systematically studied, the effects of these agents on manometric parameters in the oesophageal body may be minimal[141,142] The calcium antagonists, because of their actions on smooth muscle, have been reported to be of benefit. However, most reports are uncontrolled and anecdotal[143–146]. When a placebo control was employed, nifedipine was no better in the management of chest pain despite its significant effects on motility[147]. In view of the poor and unreproducible nature of the effects of these agents and the high incidence of psychiatric disorders, Clouse *et al*. studied the role of antidepressant therapy in patients with oesophageal contraction abnormalities[148]. As with their previous study[124], they did not separate diffuse oesophageal spasm patients from others with less classical abnormalities on manometry. They chose to study trazodone hydrochloride because it has no known effect on oesophageal motility. Patients receiving trazodone hydrochloride reported a significantly greater improvement than those receiving placebo. The response was varied, and both treatment and placebo groups had a high response rate. As with other studies, response was not associated with manometric changes on repeat testing

When symptoms are frequent, severe and do not respond to reassurance and/or medical management, myotomy may be necessary. The surgical management of diffuse oesophageal spasm is controversial. Because of the rarity of the disease, there are only three series reported of more than 15 patients[149–151], and only one with 5-year follow-up[151]. Of 149 cases reported, excellent results were obtained in 67 per cent (range 48·5–85·7 per cent)[138,149–155]. No specific criteria for selecting patients for surgery are suggested. The main areas of controversy centre on the extent of myotomy employed and the necessity of adding a hernia repair. Henderson *et al.* argue that the myotomy should be performed through the left chest and that it should extend from the proximal stomach to the apex of the chest[151]. Their reason for the left approach is to facilitate a total fundoplication hernia repair. The choice of myotomy extending to the apex of the chest is supported by autopsy studies, which demonstrate that smooth muscle is predominant over striated muscle up to the lower half of the upper oesophagus[151]. Unfortunately in Henderson's most recent report insufficient detail is given of the preoperative manometric findings, and one of his patients had ulcerative oesophagitis and two had an oesophageal stricture. Ellis *et al.* on the other hand argue for preservation of the lower oesophageal sphincter and limiting the extension of the myotomy to the distal two-thirds of the oesophagus[149].

Nutcracker oesophagus

Also known as symptomatic oesophageal peristalsis, the nutcracker oesophagus represents the most common oesophageal motility disorder. The proportion of patients with nutcracker oesophagus has increased as more patients with angina-like chest pain of non-cardiac origin are investigated for oesophageal disease. Nutcracker oesophagus accounts for 28–45 per cent of motor disorders in patients with non-cardiac angina-like chest pain[112,156–158].

Typically patients with nutcracker oesophagus present with central chest pain which may radiate to the epigastrium, into the neck or down the left arm[159]. Often the patients relate symptoms to exertion, hence their referral to the cardiologist[160]. Although dysphagia may be present[120,161] it is not as frequent as in diffuse oesophageal spasm (50–70 *versus* 100 per cent)[151]. It has been suggested that nitrates may be of benefit, particularly during an episode of pain, and this leads to further diagnostic difficulty since the cardiologist usually interprets this as further evidence of underlying ischaemic heart disease.

Nutcracker oesophagus is defined as the presence of high amplitude peristaltic waves in the distal oesophagus in a patient with symptoms of chest pain and/or dysphagia[162–164] The presence of normal peristalsis separates this disorder from classic diffuse oesophageal spasm. The peristaltic waves are usually prolonged and may be multi-peaked, though more often they are single-peaked[165]. To make a diagnosis of nutcracker oesophagus a full evaluation of the oesophagus must be undertaken to exclude coexisting pathology. When the manometric profile of nutcracker oesophagus is found in association with other oesophageal pathology such as reflux oesophagitis or stricture we should not make the diagnosis. The diagnostic criteria of nutcracker oesophagus vary in different institutions. The original description of this disorder required a mean peristaltic wave amplitude of > 120 mmHg, averaged over ten wet swallows in the distal 5 cm of the oesophagus[121,156,162]. Traube *et al*[166] required a value > 140 mmHg, and in a recent report Ott *et al.*[167] required a value > 180 mmHg. The mean(s.d.) normal distal amplitude in Ott's study, derived from a group of 95 healthy subjects, is 100(80) mmHg. Gelfand and Botoman consider a mean amplitude of ± 150 mmHg as diagnostic[168]. These variations arise from differences in normal populations rather than differences in manometric technique. At present we consider a mean amplitude of the peristaltic wave ⩾ 150 mmHg in the lower 5 cm of the oesophagus as diagnostic of nutcracker oesophagus. Drane *et al.* attempted to correlate manometric findings with evidence of poor bolus clearance from the distal oesophagus[169]. In patients with mean peristaltic amplitudes between 120 and 150 mmHg, only 50 per cent had evidence of delayed transit using radionuclide oesophageal scintigraphy, while 81 per cent of those with amplitudes ⩾ 150 mmHg had abnormal radionuclide oesophageal scintigraphy. Agreement between the two techniques was far from good

These and the results of other radionuclide oesophageal scintigraphy studies[170,171] suggest that the functional disorder of nutcracker oesophagus has a pathological basis. However, variability in the manometric results in nutcracker oesophagus is a significant problem. Spurling *et al.* found a high variability in manometric results when patients were studied on multiple occasions over a 1-month period[172]. Drane *et al.* reported that 31 per cent of patients on repeat examination were classified as normal[169], and Johnson *et al.* reported normal manometry in three of 11 patients on longer follow-up[173] As in diffuse oesophageal spasm, there is often a lack of temporal correlation between symptoms and manometric abnormalities, even when the symptoms are reproduced during provocation tests[119,174]. Abnormal waves are seen during asymptomatic periods and alteration of the manometric profile during symptoms is often absent[174] Furthermore, relief of chest pain, the hallmark of the disease, does not coincide with the reduction in the amplitude of the oesophageal contractions[148]. Although patients frequently relate symptoms to effort, we have demonstrated that the amplitude of peristaltic contractions in patients with nutcracker oesophagus during exercise is, paradoxically, within normal limits[175]. These findings indicate that the relationship of chest pain and high-amplitude oesophageal peristaltic waves is not a causal one.

Richter and colleagues, using balloon distension to study the mechanism of oesophageal pain, found that non-cardiac chest pain was related to lower pain thresholds, a mechanism independent of oesophageal contractions, wall tone or wall resistance[176,177]. Support for this abnormal perception of distension comes from Edwards in a report entitled 'The tender oesophagus'[178], and Vantrappen *et al.* who describe the condition as the irritable oesophagus[179]. There are striking similarities between nutcracker oesophagus and the irritable bowel syndrome. Patients with irritable bowel syndrome experience lower abdominal pain with rectal balloon volumes not generally perceived by normal subjects[180,181] or anxious patients without bowel symptoms[182]. No evidence of abnormal muscular activity or increased gut wall tension was found in these studies. The pathogenesis of the lower visceral pain threshold in patients with nutcracker oesophagus and irritable bowel syndrome is poorly understood. In three separate investigations the prevalence of subjects with psychiatric illness ranged from 70 to 92 per cent in patients with the irritable bowel syndrome but was only 18 per cent in medically ill controls[183–185]. A preliminary report comparing a small group of patients having nutcracker oesophagus with patients who had irritable bowel syndrome and asymptomatic subjects suggested similarities between the two symptomatic groups[186] This was further supported by a report from Clouse and Lustman, in which psychiatric illness was present in >80 per cent of patients with symptomatic high-amplitude oesophageal contractions, compared with 31 per cent of patients with normal manometric findings[124]. The same diagnoses (depression, anxiety disorder and somatization disorder) were largely responsible for the increased prevalence of psychiatric illness in both nutcracker and irritable bowel syndrome patients[124]. Patients in both groups were predominantly women (2·1). Intense environmental stimuli can provoke tertiary contractions in the oesophageal body, and emotional tension or psychic stress can evoke changes in oesophageal motor activity[187].

It is possible that high-amplitude contractions may be an unassociated marker of this pain syndrome[188]. It is possible that nutcracker oesophagus may not be a marker for oesophageal disease or oesophageal-related pain. It is also possible that the high incidence of psychiatric illness may be the result of, rather than the cause of, a disorder which perplexes not only the patient but also the attending physician. Patients with coronary artery spasm (Prinzmetal's angina) have a high incidence of motor disorders of the oesophagus[189]. A common pathophysiology has been suggested, as both coronary artery spasm and oesophageal contractions are mediated by alpha, histamine and muscarinic receptors[189,190] Ergonovine, which is widely used for diagnostic provocation of coronary artery spasm, is capable of inducing abnormalities in oesophageal contractions. Evans and Lum demonstrated that hyperventilation is an important cause of chest pain in patients with normal coronary arteries[191]. This hyperventilation was capable of inducing impressive electrocardiographic S–T changes. Rasmussen *et al* reported that hyperventilation could aggravate both coronary artery spasm and oesophageal motor activity[189]. Spears and Koch reported 18 patients with mitral valve prolapse, 12 of whom had motor disorders on oesophageal manometry[192]. Sataline recently reported an association between mitral valve prolapse and irritable bowel syndrome[193]. Association between nutcracker oesophagus and biliary dyskinesia has also been reported[194]. For the moment it would seem wise to reserve judgement as to whether the nutcracker oesophagus represents a true primary disorder of oesophageal motility, a reflection of disease distant from the oesophagus, or a new manifestion of the irritable bowel syndrome.

Obviously the treatment of nutcracker oesophagus is somewhat empirical as many reports are anecdotal. The treatment of non-cardiac chest pain of oesophageal origin in general is difficult. Ward *et al.* reported long-term follow-up of symptomatic status of patients with non-cardiac chest pain and specifically addressed the question: Is diagnosis of oesophageal aetiology helpful[195]. They concluded, after a follow-up of mean length 21·8 months, that patients diagnosed as having an oesophageal cause for their non-cardiac chest pain usually continued to have recurrent pain. Furthermore, a specific diagnosis did not increase the likelihood of pain resolution. However, patients who understood that the oesophagus was the source of their pain were significantly less likely to feel disabled by their pain and to require continued evaluation. These findings were independent of any treatment programme. Similar findings have been reported by Burns *et al.*[196]. Suggested treatments include short- and long-acting nitrates[105], calcium antagonists[197,198], antidepressants[148], psychological support and reassurance[148], physiotherapy to restore normal breathing patterns[191], dilatation[199], and even surgical myotomy in refractory cases[200]. Symptomatic improvement with bougienage appears to be mainly a placebo effect, as Winters *et al.* reported improvement when dilated by a dilator of such small diameter as to be a sham dilator[199]. Traube *et al.* advocate long myotomy for refractory cases and report their results in four cases[200]. It is, however, far from clear whether the symptom relief can be attributed to the myotomy, as three of the four cases had evidence of abnormal gastro-oesophageal reflux, no 24-h pH studies were performed, and all three cases underwent simultaneous antireflux surgery. This underlines the importance of excluding associated oesophageal pathology before diagnosing nutcracker oesophagus. Richter and Castell stress that true intractability must be quite rare as they have not felt it necessary to refer a single patient with nutcracker oesophagus for myotomy despite seeing over 100 cases in a 3-year period[201].

Conclusion

Manometry is the best available method for diagnosing the motor disorders of the oesophagus. The criticism that manometric techniques differ widely among institutions has been largely overcome since the introduction of the low-compliance hydraulic method. As a result the comparison of manometric profiles is made possible between institutions. What is now required is a strict adherence to the accepted categories of abnormalities As a result confusion will be less likely. With the advent of a completely ambulatory system for performing manometry it is reasonable to assume that manometry will closely reflect normal events in the oesophagus and allow better correlation between symptoms and abnormal motility, just as ambulatory pH monitoring has revolutionized the understanding of gastro-oesophageal reflux.

Even if a classic abnormal motor pattern is detected on manometry this is insufficient evidence on which to base a diagnosis. All the abnormal manometric profiles can be detected in other situations. The most important examples are pseudoachalasia secondary to tumours of the cardia and motor disturbances associated with gastro-oesophageal reflux. Every form of motor disorder has been described in association with gastro-oesophageal reflux Patients should rarely if ever be diagnosed as having diffuse oesophageal spasm or nutcracker oesophagus when there is evidence of abnormal gastro-oesophageal reflux or complications of reflux such as stricture. Future reports should exclude all cases associated with gastro-oesophageal reflux and include results of pH monitoring Non-specific oesophageal motility disorders is the general term applied to abnormal contraction patterns identified at manometry which do not fit into any recognized category. These aberrant patterns we sometimes find in association with non-cardiac chest pain, but their clinical significance is not understood at present.

The results of myotomy for achalasia of the lower oesophageal sphincter and for upper oesophageal sphincter dysfunction associated with a diverticulum are excellent. The outcome of myotomy for upper sphincter dysfunction without a diverticulum is less certain. Surgery is rarely indicated in diffuse oesophageal spasm; nutcracker oesophagus should be treated conservatively and surgery is never indicated. Advances in the neurophysiology of the oesophagus in these conditions will lead to a better understanding of their possible inter-relationships and clarify the therapeutic options.

Abdominal pain: a surgical audit of 1190 emergency admissions

T. T. Irvin

Department of Surgery, Royal Devon and Exeter Hospital (Wonford), Barrack Road, Exeter, Devon EX2 5DW, UK
Correspondence to:
Mr T. T. Irvin

In an audit of 1190 emergency admissions with abdominal pain (1166 patients) in a general surgical unit, the diagnosis was non-specific abdominal pain (NSAP) in 415 (35 per cent), acute appendicitis in 200 (17 per cent) and intestinal obstruction in 176 (15 per cent). The largest number of admissions occurred in the age groups 10–29 years (31 per cent) and 60–79 years (29 per cent). Surgical operations were performed in 551 patients (47 per cent) and there was a 16 per cent incidence of unnecessary appendicectomy (22 per cent in the age group 20–29 years). Fifty-one deaths resulted in a 30-day hospital mortality rate of 4·4 per cent and a perioperative mortality rate of 8 per cent. The mortality rate increased significantly in patients aged $\geqslant 60$ years, and patients aged 80–89 years had a perioperative mortality rate of 20 per cent. The causes of perioperative death included laparotomy for inoperable disease (28 per cent), ruptured abdominal aortic aneurysm (23 per cent), perforated peptic ulcer (16 per cent) and colonic resections (14 per cent). The perioperative mortality rates for ruptured aneurysm and perforated ulcer were 71 and 23 per cent respectively. The duration of inpatient stay increased significantly with the age of the patients, including those with NSAP. The results of the study indicate a need to review the methods of management of ruptured aortic aneurysm and perforated peptic ulcer, the methods of diagnosis of appendicitis, particularly in young females, and the factors that determine the duration of stay of patients suffering from NSAP.

Keywords: Acute abdomen, abdominal pain

The majority of emergency admissions to surgical wards are patients complaining of abdominal pain. Surprisingly, there is comparatively little information regarding the clinical spectrum of disease in these patients and the outcome after admission to hospital. Most studies of the acute abdomen have been confined to patients in specific age groups[1–3], to patients with specific diseases[4–7] or particular types of acute presentation[8,9], or to patients who fail to survive a surgical operation[10]. The Confidential Enquiry into Perioperative Deaths (CEPOD)[10] included deaths after urgent or emergency abdominal operations for a range of acute disorders but the study provided no information regarding the relative risks attached to the various disorders which present as an acute abdomen.

For the last 4 years an audit of emergency admissions of patients with abdominal pain in one surgical unit has been carried out; this was to determine the clinical spectrum of disease, the outcome of treatment or investigation, and the implications for bed occupancy.

Patients and methods

The study included all emergency admissions of patients complaining of abdominal pain in one surgical unit of a district general hospital during the period from January 1984 to December 1987. The unit has 30 adult general surgical beds and access to a small number of emergency beds within a paediatric ward. The predominant interest of the unit is gastrointestinal surgery, and the medical staff include one consultant surgeon, one rotation registrar or senior registrar, one senior house officer, and one preregistration house surgeon. The district general hospital serves a population of 302 400[11], and the surgical unit has a 1 day in 5 commitment to admit all surgical emergencies arising within the district during a 24-h period, including vascular and urological cases.

Method of audit

A standard form of discharge summary was used for all admissions including details of the mode of clinical presentation, the results of investigations, the methods of treatment, the operating surgeons, the clinical outcome, and the final clinical diagnosis. A diagnosis of 'non-specific abdominal pain' (NSAP)[8] was recorded when no cause for the abdominal pain was found. The clinical details were transferred to a study proforma for analysis. The dictation of discharge summaries and completion and analysis of the proforma occupied approximately 300 man-hours.

Statistical analysis

The χ^2 test, Fisher's exact test, and the t test for unpaired data were used in the analysis of different variables.

Results

Admissions

During the 4-year period 1166 patients were admitted with abdominal pain. Twenty-three patients were admitted more than once (one patient was admitted on three occasions) resulting in a total of 1190 admissions. There were 579 male patients and 587 female patients of mean age 46 years (range, from 2 months to 98 years), and the peak age groups for emergency admission were 10–29 years (31 per cent of patients) and 60–79 years (29 per cent of patients). There was no significant difference in the rates of admission through different months of the year although there was a slightly increased rate in August due to an influx of visitors in the Exeter area

Clinical diagnosis

The final clinical diagnoses in the 1190 admissions are shown in *Table 1*. The most common diagnoses were non-specific abdominal pain (NSAP), acute appendicitis, and intestinal obstruction; but there were significant differences in the incidence of the presenting illnesses in patients aged <60 years and those aged $\geqslant 60$ years. Intestinal obstruction was the most frequent diagnosis in patients aged $\geqslant 60$ years (28·0 per cent of admissions), followed by NSAP (22·5 per cent), complications of cholelithiasis (8·9 per cent) and colonic diverticular disease

Table 1 *Diagnoses in 1190 admissions for abdominal pain, and in patients aged <60 years and ≥60 years*

	No. of admissions			
Diagnosis	Total (n=1190)	Age ≥60 years (n=471)	Age <60 years (n=719)	P*
Non-specific abdominal pain	415 (34·9)	106 (22·5)	309 (43·0)	<0·001
Acute appendicitis	200 (16·8)	20 (4·2)	180 (25·0)	<0·001
Intestinal obstruction	176 (14·8)	132 (28·0)	44 (6·1)	<0·001
Urological	70 (5·9)	15 (3·2)	55 (7·6)	<0·01
Cholelithiasis	61 (5·1)	42 (8·9)	19 (2·6)	<0·001
Colonic diverticular disease	46 (3·9)	40 (8·5)	6 (0·8)	<0·001
Abdominal trauma	37 (3·1)	2 (0·4)	35 (4·9)	<0.001
Abdominal malignancy	36 (3·0)	26 (5·5)	10 (1·4)	<0·001
Perforated peptic ulcer	30 (2·5)	20 (4·2)	10 (1·4)	<0·01
Pancreatitis	29 (2·4)	18 (3·8)	11 (1·5)	<0·02
Exacerbated peptic ulcer	17 (1·4)	9 (1·9)	8 (1·1)	n.s.
Ruptured aortic aneurysm	15 (1·3)	14 (3·0)	1 (0·1)	<0·001
Gynaecological	13 (1.1)	1 (0·2)	12 (1·7)	0·002
Inflammatory bowel disease	10 (0·8)	5 (1·1)	5 (0·7)	n.s.
Medical (pneumonia, pulmonary embolism, myocardial infarction, etc.)	10 (0·8)	5 (1·1)	5 (0·7)	n.s.
Mesenteric vascular occlusion	7 (0·6)	7 (1·5)	0	0·003
Gastroenteritis	4 (0·3)	0	4 (0·6)	n.s.
Miscellaneous	14 (1·2)	9 (1·9)	5 (0·7)	n.s

Values in parentheses are percentages, *statistical significance of differences between admissions aged ≥ 60 years and those aged <60 years (χ^2 and exact probability tests), n.s., not significant

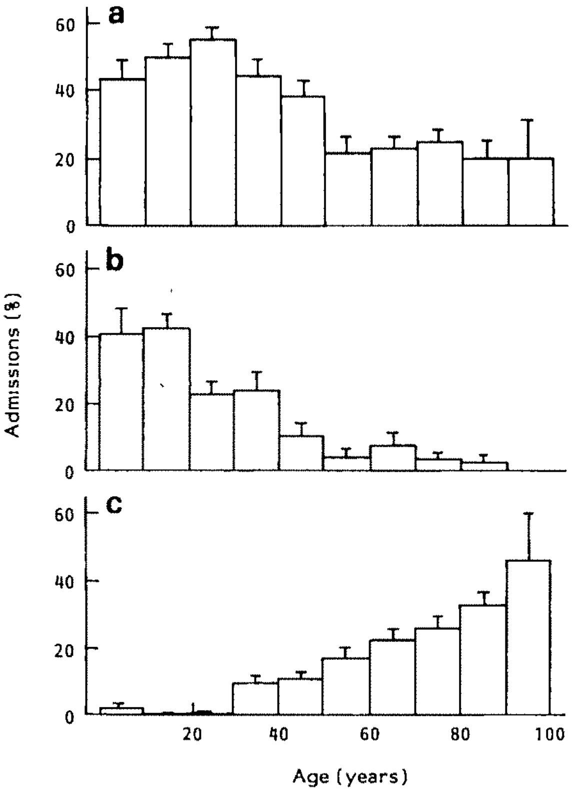

Figure 1 *Age distribution of admissions for* **a** *non-specific abdominal pain,* **b** *acute appendicitis and* **c** *intestinal obstruction (percentages + 95 per cent confidence intervals)*

(8·5 per cent), and acute presentation of various types of abdominal malignancy (5·5 per cent). NSAP (43·0 per cent) and appendicitis (25·0 per cent) were the most frequent diagnoses in patients aged <60 years. The age distribution of the admissions with NSAP, appendicitis, and intestinal obstruction is shown in *Figure 1* and it is apparent that the peak for admissions in the 10–29 age range is due to the large numbers of cases of NSAP (50·8 per cent of admissions) and appendicitis (33·0 per cent of admissions).

The causes of intestinal obstruction are shown in *Table 2*.

Table 2 *Causes of intestinal obstruction*

Cause	No of admissions (n=176)
External hernia	51 (29·0)
Adhesions	37 (21·0)
Carcinomatosis	35 (19·9)
Colonic carcinoma	34 (19·3)
Colonic diverticular disease	4 (2·3)
Volvulus (sigmoid/caecal)	4 (2·3)
Crohn's disease	3 (1·7)
Pseudo-obstruction	3 (1·7)
Miscellaneous*	5 (2·8)

Values in parentheses are percentages; * cause uncertain (no operation) in 3, gallstone ileus in 1 and cystic fibrosis in 1

Interestingly, large bowel obstruction due to colonic carcinoma (19·3 per cent of admissions) was slightly less common than small bowel obstruction caused by external hernia, adhesions, and abdominal carcinomatosis.

Surgical operations

Five hundred and fifty-one of the patients (47·3 per cent) underwent a surgical operation. Using the CEPOD classification[10], 26 (4·7 per cent) were emergency operations (immediate, potentially life-saving procedures, e.g. for ruptured aortic aneurysm and abdominal trauma), 467 (84·8 per cent) were urgent operations (operation performed after adequate resuscitation or preparation, e.g. operations for intestinal obstruction or peritonitis), and 58 (10·5 per cent) were scheduled operations (operation performed as an elective procedure on a scheduled list, e.g. operations for complications of cholelithiasis or recurrent small bowel obstruction). Scheduled operations were more common in older patients (15·8 per cent of operations in patients aged ≥60 years, $\chi^2 = 12{\cdot}49$, $P < 0{\cdot}001$), mainly owing to an increased incidence of complications of cholelithiasis and acute presentation of gastrointestinal malignancies

The most common operations were appendicectomy (35·6 per cent), operations for strangulated external hernia and other causes of small bowel obstruction (22·1 per cent), colonic resections (12·3 per cent), and urgent or scheduled operations for cholelithiasis (5·6 per cent). The incidence of unnecessary appendicectomy in different age groups was related to the age incidence of NSAP. In total, 15·5 per cent of appendices

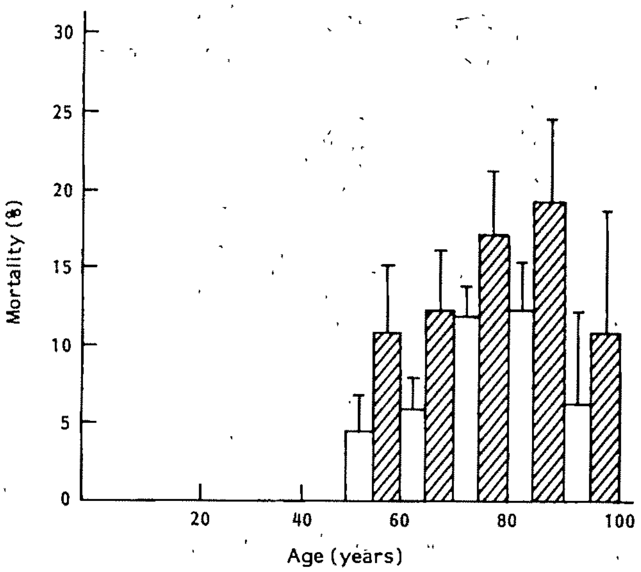

Figure 2 *Age distribution of hospital (☐) and perioperative (■) mortality (percentages and 95 per cent confidence intervals)*

removed proved to be normal and there was a 22·4 per cent incidence in patients aged 20–29 years. Moreover, the error predominantly occurred in female subjects: 77 per cent of patients aged <30 years undergoing an unnecessary appendicectomy were female. Three hundred and twenty operations (58·1 per cent) were performed by a registrar or senior registrar (with or without consultant supervision), 122 (22·1 per cent) were performed by the senior house officer (usually an appendicectomy), and 109 (19·8 per cent) were performed by the consultant.

Mortality

Fifty-one patients died in hospital, resulting in a 30-day hospital mortality rate of 4·4 per cent and a perioperative mortality rate of 7·8 per cent. The mortality rates were age-related (*Figure 2*): the perioperative mortality rate was 12·3 per cent in patients aged 60–69 years, 17·4 per cent in patients aged 70–79 years, and 19·7 per cent in patients aged 80–89 years. The hospital and perioperative mortality rates for patients aged <60 years were 0·7 per cent and 1·6 per cent respectively.

There were eight non-operative deaths. Two patients died during conservative treatment of subacute small bowel obstruction caused by adhesions: one patient (aged 78 years) inhaled gastric contents, and the other patient (aged 60 years) suffered a myocardial infarction. Two patients, aged 72 years and 77 years, died from acute necrotizing pancreatitis, one also suffering a cerebrovascular accident. One patient aged 78 years died from a massive pulmonary embolism, and another aged 82 years died from irreversible congestive cardiac failure. Both patients presented as abdominal emergencies and the absence of abdominal pathology was confirmed at autopsy. Two patients, aged 72 years and 80 years, who were admitted with established incurable malignant disease, died in hospital, in one case as a consequence of the malignancy and in the second case due to a ruptured abdominal aortic aneurysm.

There were 43 perioperative deaths, and in 25 cases (58 per cent) the patient was aged >75 years. The surgical operations were performed by the consultant in ten cases (23 per cent) and by the senior registrar or registrar in 33 cases (77 per cent). The types of surgery resulting in the 43 deaths are listed in *Table 3*. The highest proportion of the deaths (28 per cent) occurred in patients found to have inoperable diseases (massive intestinal infarction or carcinomatosis), closely followed by ruptured aortic aneurysm (23 per cent of deaths). Operations for perforated peptic ulcer and urgent colonic resections accounted for 16 and 14 per cent of deaths respectively. There were no deaths after operations for cholelithiasis or appendicectomy but one patient (aged 77 years) died from a myocardial infarction during an unnecessary laparotomy for suspected ruptured aortic aneurysm.

The perioperative mortality rate for ruptured aortic aneurysm was 71 per cent. The operations were performed by the consultant in six cases and by a senior registrar in four cases. Three of the ten deaths resulted from exsanguination or cardiac arrest during the operation, three were related to postoperative haemorrhage and coagulopathy, and four deaths resulted from acute renal failure. Eight of the ten patients were aged >75 years.

The perioperative mortality rate for perforated peptic ulcer was 23 per cent. The seven deaths occurred in patients with pyloroduodenal ulceration, and six of the seven perforations were treated by simple suture; the remaining patient with a very large perforation and coexisting haematemesis and melaena underwent a Pólya gastrectomy. The operations were performed by a registrar or senior registrar in six cases and by the consultant in one case. Five deaths resulted from cardiac or circulatory failure, and two deaths were related to reperforation of the ulcer following simple suture. Five of the seven patients were aged >75 years.

The perioperative mortality rate for urgent colonic resections was 9 per cent. Three deaths occurred in patients with faecal peritonitis resulting from perforated diverticular disease, two deaths occurred after resections of colonic tumours (one obstructing and one perforated), and one death occurred after a sigmoid resection for volvulus. All the operations were performed by a registrar or senior registrar. The causes of death included uncontrolled sepsis and multiple organ failure (four cases with faecal peritonitis), congestive cardiac failure (one case), and pulmonary embolism (one case). All six patients were aged >75 years.

Duration of stay

The 1190 admissions resulted in a total bed occupancy of 8096 inpatient days. Patients aged 70–79 years were the major users of beds (1849 inpatient days) and patients aged $\geqslant 70$ years accounted for 39 per cent of the bed occupancy. The mean duration of stay increased significantly after the age of 40 years ($t=10{\cdot}45$, $P<0{\cdot}001$), and the duration of stay for patients with NSAP was also age-related (*Figure 3*). Patients with NSAP aged $\geqslant 70$ years remained significantly longer in hospital ($t=11{\cdot}53$, $P<0{\cdot}001$) and they were more frequently subjected to definitive inpatient investigations (endoscopy, barium study, ultrasound, etc.): 76 per cent of patients aged $\geqslant 70$ years underwent such investigations compared with 32 per cent of patients aged <70 years ($\chi^2=48{\cdot}06$, $P<0{\cdot}001$).

Discussion

NSAP was the most common diagnosis in emergency admissions (35 per cent of admissions), but there were age-related differences in the incidence of NSAP and the other diagnoses; intestinal obstruction, most frequently due to a strangulated external hernia, was the most common diagnosis

Table 3 *Nature of surgery resulting in 43 perioperative deaths*

Nature of surgery	No. of cases	No. of deaths
Laparotomy and closure (inoperable)*	16	12 (75·0)
Ruptured aortic aneurysm	14	10 (71·4)

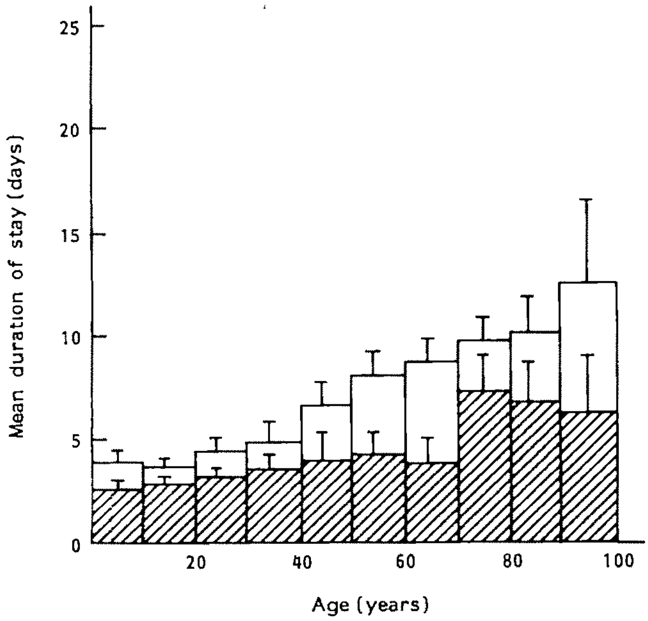

Figure 3 *Mean duration of stay for each age group (all cases (□) and non-specific abdominal pain admissions (■)) and 95 per cent confidence intervals*

in the elderly (28 per cent of admissions in patients aged $\geqslant 60$ years). Moreover, there were two peak age groups for emergency admission: 10–29 years (31 per cent of patients) when the most common diagnoses were NSAP (51 per cent) and acute appendicitis (33 per cent), and 60–79 years (29 per cent of patients) when the common diagnoses were intestinal obstruction (25 per cent), NSAP (23 per cent), cholelithiasis (9 per cent), colonic diverticular disease (9 per cent), and various non-obstructing malignancies. Gilmore *et al* [12] also witnessed a bimodal age distribution in emergency surgical admissions although the causes of admission were not documented.

Less than half (47 per cent) of the patients in this study underwent a surgical operation but there was a 16 per cent incidence of unnecessary appendicectomy chiefly due to misdiagnosis of appendicitis in patients suffering from NSAP. The problem was greatest in young adults (22 per cent incidence in the age range 20–29 years) and particularly in young females, although a minority were found to have gynaecological pathology accounting for their symptoms. Previous studies have recorded an incidence of unnecessary appendicectomy ranging from 8 to 33 per cent[13] and it has been suggested that the accuracy of diagnosis may be improved either by the use of laparoscopy[14–16] or by the use of a computer database and application of Bayesian probability[8,9,17]. Neither method is widely used by general surgeons, and they were not used during the period of this study.

Gynaecologists regularly use laparoscopy in the diagnosis of pelvic or lower abdominal pain, and recent studies by general surgeons have suggested that laparoscopy has considerable value in the diagnosis of the acute abdomen. Thus, in a group of 36 young female patients presenting with clinical features suggestive of appendicitis, Deutsch *et al.*[15] avoided inappropriate laparotomy in 12 cases by the use of diagnostic laparoscopy, and Paterson-Brown *et al.*[16] observed that laparoscopy prevented an inappropriate clinical decision in six of 31 patients presenting with acute abdominal pain.

Computers aid the diagnosis of abdominal pain by providing probabilities for different diagnoses based on a comparison of the presenting clinical features in each case with a database of features associated with specific causes of abdominal pain. Single centre[8] and multicentre[9] studies suggest that such methods are of significant value in the diagnosis of abdominal pain but they have not found wide application, and a recent review[18] suggests that further research is required before computer-aided diagnosis can be widely implemented in the National Health Service in the UK. Perhaps such research should pay particular attention to the problems of diagnosis in young females with abdominal pain.

The highest proportion of perioperative deaths in this study (28 per cent) followed exploratory laparotomy for inoperable disorders such as massive intestinal gangrene resulting from superior mesenteric vascular occlusion or extensive abdominal carcinomatosis. Seymour and Pringle[19] have suggested that such patients should be discounted from mortality statistics because of their potentially non-viable status but it is possible that some perioperative deaths in patients with advanced abdominal malignancy might have been avoided by the use of laparoscopy rather than laparotomy. Like other surgeons[20,21], we have in our department used laparoscopy in the elective staging of pancreatic and oesophageal cancers, but we have no experience in the use of this technique in the assessment of malignancies presenting as an 'acute abdomen'.

Ruptured aortic aneurysm and perforated peptic ulcer, two of the least common presenting illnesses, proved to be the major causes of potentially avoidable perioperative death in this study.

Ruptured aortic aneurysm occurred in only 1·3 per cent of admissions but it was associated with a 71 per cent perioperative mortality rate. Specialist vascular units report an average hospital mortality rate of 40 per cent for this condition[22] with a range of 15–68 per cent[23], but the figure may be higher in non-specialist units and in patients aged >75 years[24]. The factors that influence the prospects of survival are accurate diagnosis, the transfer time to hospital, and the availability of skilled resuscitation and immediate, speedy surgery with an absence of technical errors[23,25]. The CEPOD report[10] recommended that all patients with aortic aneurysm should be admitted to specialist vascular units but this will not be possible in the foreseeable future due to the shortage of vascular surgeons and trainees[26]. It is our impression that many of the patients who died in Exeter were unsalvageable. Eight of the ten deaths occurred in patients aged >75 years and a significant proportion had coexisting cardiovascular disorders and underwent emergency surgery with an unstable circulation. However, it is not possible by retrospective analysis to establish the speed of transfer to hospital or the adequacy of the resuscitation or surgery. The operations were performed by surgeons of consultant or senior registrar status with experience in vascular surgery although the elective clinical interest of the unit is largely confined to gastrointestinal surgery. Anaesthetists of consultant or senior registrar status were involved in the resuscitation of the patients, and the survivors of surgery were nursed in the intensive therapy unit However, the results of this audit have prompted the development of a prospective study of ruptured aneurysm and a clearly defined strategy to minimize delay in the transfer of patients to the operating theatre.

Perforated peptic ulcer occurred in 2·5 per cent of admissions but it was associated with a perioperative mortality rate of 23 per cent and accounted for 16 per cent of the perioperative deaths in this study. There have been important epidemiological changes in the clinical presentation of perforated ulcer in recent years. The majority of patients are elderly and have acute ulcers, sometimes induced by non-steroidal anti-inflammatory drugs, and a significant proportion have coexisting medical disorders which present increased risks in surgical treatment. Recent studies of such cases have reported mortality rates in excess of 30 per cent[27–29] and it appears that a new strategy is required for the management of perforated ulcers in elderly subjects[29]. Risk factors in elderly patients such as delayed presentation, shock, and serious coexisting medical disorders are associated with an increased probability of perioperative death and there may be a case for a trial of non-operative treatment in such cases[30]. It is possible that some of the patients in this study might have survived if they had not been subjected to surgery but a prospective study is required to determine the value of case selection based on risk stratification. However, it is apparent that there is now a very limited place for definitive ulcer surgery in the management of perforation Most patients have acute pyloroduodenal perforations and these can be managed by simple suture of the perforation and administration of histamine antagonist drugs[31]. Interestingly, such treatment did not prevent two reperforations in this study although both patients received intravenous ranitidine during surgery and after operation. Perhaps faulty surgical technique was responsible for the outcome in these cases.

Urgent colonic resections were associated with a 9 per cent perioperative mortality rate, a rate which is substantially lower than the 17–38 per cent mortality rates reported in recent studies[7,32,33]. The majority of deaths in this study occurred in elderly patients with faecal peritonitis resulting from perforated diverticular disease or perforated colonic carcinoma, despite resuscitation, expeditious surgery, intensive care, and antibiotic therapy. However, one death due to pulmonary embolism may be attributed to the absence of low-dose heparin prophylaxis in a subject with an increased risk of this complication.

The resource implications of patients admitted with abdominal pain were identified in the study of bed utilization. The average duration of stay increased with age, and patients in the age group 70–79 years had the greatest bed occupancy (23 per cent of the total inpatient days) In a study of elective and emergency admissions to surgical wards, Seymour[34] found that the duration of stay increased progressively after the age of 64 years and patients aged ⩾75 years remained in hospital for a mean of 10 days. There is a certain sense of inevitability about such observations in the elderly. However, this study revealed that at least 20 per cent of elderly patients admitted as abdominal emergencies had a diagnosis of NSAP, and these patients also remained significantly longer in hospital by comparison with younger patients with NSAP. It is not clear if the elderly patients had more persistent pain or if the delay in discharge was due to uncertainty on the part of the clinicians with regard to the diagnosis. It is apparent that the elderly patients were more often subjected to radiological and endoscopic examinations, and such caution is perhaps justified since DeDombal *et al.*[35] found that malignant disease was the cause of NSAP in 10 per cent of admissions aged >50 years. Nevertheless, the group of elderly patients with NSAP deserves further study even if the outcome is simply more expeditious investigation and earlier discharge from hospital.

Various methods of self-assessment have been recommended for quality assurance in general surgery[10,36], and the type of audit described in this study has considerable educational value. It enables the clinician to determine the proportional risks attached to different types of surgery and disease and the attendant resource implications; and it permits a more informed discussion of the case material presenting in weekly mortality and morbidity meetings. However, the value of audit in quality assurance can be gauged only by ongoing continuous studies which demonstrate actual improvements in patient care, and manual methods of audit are too laborious for the frequent analyses required in such studies. There is a need for the careful planning of software programs and the development of computerized systems of audit in each health district. These could be developed on existing microcomputer programs[37] or, preferably, as part of a new Department of Health regional strategy for computer studies

Infirmary, Edinburgh EH3 9YW, UK

The cause, management and outcome of 23 patients with a pancreatic fistula following acute pancreatitis are reviewed. Nineteen patients developed an external fistula following necrosectomy or drainage of a pancreatic abscess or pseudocyst; four of these patients died. In the 15 survivors spontaneous closure occurred in 11 cases with low output fistulae; operative intervention was needed in the four cases with high output fistulae. Four patients with internal fistulae had not undergone previous surgery; two of them had a pancreaticopleural fistula with associated pancreaticogastric fistulae, while two had pancreatic ascites. All four of these patients required surgical intervention and one died.

Keywords: Pancreatic fistula, pancreatic ascites, acute pancreatitis

Pancreatic fistulae follow pancreatic duct disruption and may develop as a complication of pancreatic disease or injury. If disruption occurs during an attack of acute pancreatitis the escaping fluid may be walled off by the surrounding viscera to form a pseudocyst or an abscess may develop Fistula formation may follow surgical intervention for necrosectomy, or drainage of an abscess or pseudocyst. Fistulae may drain spontaneously into adjacent hollow viscera or communicate with the body surface externally. Less frequently, the duct disruption or rupture of a communicating pseudocyst remains free leading to pancreatic ascites or pleural effusion[1–3].

We present our experience of 23 patients with pancreatic fistulae that developed following an attack of acute pancreatitis; all were treated in Glasgow Royal Infirmary between January 1971 and July 1988.

Patients and methods

A fistula is usually defined as a communication between two surfaces lined by epithelium For the purpose of the present review the term is used to encompass communication between the pancreatic duct and the skin (external fistula), between the pancreatic duct and hollow viscera, and between the pancreatic duct and the peritoneal or pleural cavities (internal fistula). Duodenal fistulae are not included Patients were included in this review if the presence of a fistula was confirmed by a fistulogram or endoscopic retrograde cholangiopancreatography (ERCP) or if the output contained an amylase concentration higher than that of serum. External fistulae were classified as high output if the volume collected exceeded 200 ml per day. The aetiology of the acute pancreatitis and the number of positive prognostic factors were recorded[4]. The timing of onset of the fistula in relation to any previous operation or attack of pancreatitis was noted. The fistula was then classified as postoperative or spontaneous

Review of the prospectively documented experience of acute pancreatitis in Glasgow Royal Infirmary between January 1971 and July 1988 showed that 23 patients had fulfilled the above criteria Six of the patients had been referred from other institutions for management of necrotizing pancreatitis or pancreatic abscess The remaining 17 patients had been admitted initially to Glasgow Royal Infirmary

Of the 23 patients, 14 were men and nine were women, with a mean age of 40 years (range 17–67 years). Pancreatitis was considered to have been due to gallstones in 12 patients, from whom stones were recovered at operation. Eight patients had alcohol-induced pancreatitis, one patient had a duodenal tumour, and no precipitating cause could be identified in two patients. Three of the patients with internal fistulae have been reported previously[5].

External fistulae

Nineteen patients had postoperative external fistulae discharging through an abdominal wound or drain site All had three or more positive prognostic factors denoting severe acute pancreatitis The fistulae followed necrosectomy (nine patients), drainage of pancreatic abscess (eight patients) and drainage of pseudocysts (two patients) Fluid amylase estimations were available in eight patients and concentrations ranged from 1300 to 292 000 units per litre. Fistulograms were performed in 12 patients and showed that four of them also had internal fistulae (two in the colon, one in the stomach and one in the proximal small intestine). Two patients had ERCP demonstrating disruption of the main pancreatic duct system in the body and tail of the gland. Another patient was found to have a completely transected pancreatic duct at necrosectomy. The diagnosis in the remaining four patients with external fistulae was based on the high amylase levels Four of the patients had high output fistulae.

Internal fistulae

Four patients had six internal fistulae. Two of them had pancreaticoperitoneal fistulae while two presented with pleural effusions caused by pancreaticopleural fistulae ERCP in all four patients showed disruption of the pancreatic duct and free passage of contrast medium into the peritoneal or pleural cavity It also showed pancreaticogastric fistulae in the two patients with pancreaticopleural fistulae. Aspiration of peritoneal fluid in the two patients with pancreatic ascites gave fluid amylase concentrations of 75 000 and 72 600 units per litre respectively. Pleural fluid amylase concentration (125 000 units per litre) was measured in one man with a pancreaticopleural fistula

Results

Management was classified as conservative or operative. Conservative management followed recognized guidelines. Fistula output was collected into a drainage bag and the skin around the fistula protected by stomadhesive. Fistula output was assessed and adequate fluid replacement given. Once the fistula was established and the patient's general condition stabilized, the fistula track was displayed radiologically. The requirement for intravenous nutrition was assessed. Antibiotics were withheld unless there was evidence of septicaemia or peritoneal sepsis. Any intraperitoneal abscesses were drained. Surgery was undertaken in patients with external fistulae when it was considered that the fistula would not close spontaneously on conservative treatment. Internal fistulae draining into hollow viscera did not require surgical intervention. However, fistulae draining into the peritoneal and pleural cavities were treated surgically after stabilization of the patient.

External fistulae

Four of the 19 patients with external fistulae died, three of them in the intensive care unit after necrosectomy. One patient, a 50-year-old man, died from multiple organ failure 30 days after necrosectomy and colectomy. At operation 2 days after admission he was noted to have a completely transected pancreatic duct. He was managed by open packing with daily and then alternate day pack changes. The pancreatic duct continued to discharge until his death. The second patient was a 36-year-old woman with gallstone pancreatitis who developed a pancreaticocolocutaneous fistula following necro-

0007–1323/89/1126–03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

tizing pancreatitis and who required necrosectomy and colectomy. Two weeks later, she developed a pancreatic abscess that required drainage and open packing. She died suddenly of cardiac arrest 5 weeks after surgery; the pancreatic fistula was still discharging at the time of death. She seemed to be making a good recovery and was thought to have had a pulmonary embolus. Permission for post-mortem examination was not obtained The third patient was a 62-year-old man with gallstone associated necrotizing pancreatitis who developed a high output external pancreatic fistula following necrosectomy 3 weeks after admission. He had drainage of a peripancreatic and subphrenic abscess; 15 days later he died in multiple organ failure, 31 days after his first operation. The fistula was still present at the time of death. The fourth patient was a 40-year-old man with idiopathic pancreatitis who developed a pancreatic abscess. After drainage of the abscess he developed a postoperative low output fistula which was treated conservatively for 3 months. He then developed septicaemia which led to his death from multiple organ failure 10 days later

Spontaneous closure of the fistula occurred in 11 of the 15 surviving patients. All 11 patients had low output fistulae. The mean closure time for this group was 12·3 weeks (range 8–14 weeks). The only fistula-specific complication occurred in a 52-year-old woman with alcohol-associated pancreatitis who developed a fistula after drainage of an abscess. During conservative management she had an episode of bleeding from the fistula track, losing 70 ml of bright red blood over 4 h. There were minor repeated episodes of blood loss over the following 3 weeks but the fistula then closed spontaneously. There were no other instances of haemorrhage from the fistula.

Four of the 15 survivors required some form of operative treatment. All four had high output fistulae. A 22-year-old woman with gallstone pancreatitis developed a high output fistula after cholecystectomy and drainage of a large pancreatic abscess She also developed a pseudocyst in the head of the pancreas. After conservative therapy for 5 weeks, the somatostatin analogue SMS 201-995 (Sandostatin®, Sandoz Ltd., Basle, Switzerland) was used An initial intravenous infusion over 48 h was followed by 3 days administration of 100 μg Sandostatin subcutaneously three times a day. The fistula output ceased within 36 h, but 24 h later the fistula began to produce fluid for a further 12 h; thereafter output ceased completely. However, the pseudocyst in the head of the pancreas increased in diameter to 8 cm and became symptomatic. Operative cystduodenostomy led to complete recovery.

The three remaining patients had surgery for high output fistulae and all made an uneventful recovery. A 65-year-old man underwent distal drainage for a pancreatic abscess. He also had transduodenal resection of a large duodenal adenomatous polyp thought to have caused the pancreatic duct obstruction leading to his pancreatitis. A 27-year-old man underwent distal pancreatectomy 23 weeks after onset of a pancreatic fistula following alcoholic pancreatitis A 33-year-old man with gallstone pancreatitis had a Roux-en-Y cystjejunostomy 16 weeks after the development of a fistula following rupture of a pancreatic pseudocyst.

Internal fistulae

All four patients with an internal fistula came to surgery The one patient who died was a 60-year-old alcoholic man who presented with insidious onset of pancreatic ascites (amylase concentration 75 000 units per litre). ERCP showed complete rupture of the pancreatic duct in the midbody of the gland. The patient became very ill 48 h after paracentesis. At laparotomy he was found to have gross peritonitis following laceration of the proximal jejunum by the peritoneal lavage catheter He had distal pancreatitis with peripancreatic necrosis and obvious rupture of the main pancreatic duct. Distal pancreatectomy was performed, but the patient died 15 days after the operation in respiratory failure.

The second patient with pancreatic ascites was a 26-year-old woman with gallstone pancreatitis who had initially undergone laparotomy for abdominal pain and distension At that time the peritoneum contained 5 litres of ascitic fluid (amylase concentration 72 600 units per litre), and ERCP 15 days later showed rupture of the pancreatic duct in the body of the gland. At laparotomy 8 days after ERCP the pancreas was very soft and the site of leakage could not be identified. She made a good recovery after insertion of four soft sump drains and a feeding jejunostomy; the ascites did not recur.

Both patients with pancreaticopleural fistulae underwent distal pancreatectomy, performed 6 and 9 weeks respectively after development of pleural effusions. The first patient, a 28-year-old man, had no further accumulation while the second, a 17-year-old man, required three further pleural aspirations before his effusions resolved.

Discussion

Severe necrotizing inflammation develops in 5–15 per cent of patients with acute pancreatitis[6–9]. Many of these patients go on to develop infected pancreatic necrosis, pancreatic abscess or pseudocysts and there is current interest in the value of early surgical removal of infected necrotic material. Whether the pancreatic bed should be managed subsequently by irrigation[6], multiple drains[7] or open packing[8] is controversial. The incidence of pancreatic fistulae following such surgery ranges from 12 to 40 per cent[6–9]. The majority of these fistulae will close spontaneously as occurred in 11 of the 15 surviving patients with external fistulae in the present review. Skin care, fluid replacement, nutritional support and radiological delineation of the fistula form the cornerstones of conservative therapy, but the surgeon must have a low threshold for intervention to drain infected intra-abdominal collections.

Patients with high output fistulae, usually associated with proximal obstruction or irreversible distal gland disconnection, are more likely to come to surgery. Pancreatic resection along a line just proximal to the point of duct rupture is the usual treatment. A fistulogram may delineate pancreatic duct anatomy and identify the site of duct rupture before surgery If fistulography is unhelpful, ERCP may be used to define the pathological anatomy and plan the line of pancreatic resection

As Cameron *et al.*[2] have pointed out, internal pancreatic fistulae are probably underdiagnosed. Many patients are alcoholics, and their ascites is thought to be due to liver disease until the peritoneal fluid is checked for amylase and protein concentration[1–3,10,11]. The disrupted major pancreatic duct or related pseudocyst continues to discharge due to the absence of an active peripancreatic inflammatory response Free communication between pancreatic duct and peritoneal cavity leads to ascites which may be massive, as the pancreas normally produces over 1 litre of fluid per day If the rupture is situated posteriorly, fluid tracks into the mediastinum alongside the oesophagus or aorta. It can then rupture into the pleura resulting in effusion formation, or more rarely, the lung becomes involved with formation of a pancreaticobronchial fistula[12]. The lack of inflammatory response means that spontaneous closure is unlikely Protracted conservative therapy leaves the patient at risk of developing sepsis and it is now considered unwise to continue such treatment for more than 2–3 weeks. If conservative treatment is undertaken, it should include complete drainage of the ascites or pleural fluid and parenteral hyperalimentation. ERCP is essential to delineate the site of duct rupture or define the presence of a leaking pseudocyst in patients with such internal fistulae[5,10,12]

Pancreatic resection is indicated if surgery is needed following duct disruption in the body or tail of the pancreas, whereas Roux-en-Y cystjejunostomy or pancreaticojejunostomy can be undertaken for lesions in the head. One patient in the present series was successfully managed by insertion of soft sump drains when the site of the rupture could not be identified There is no need to extend the dissection of the fistula track into the chest in patients with a pleural fistula because disruption of the track in the course of pancreatic surgery prevents further passage of pancreatic fluid into the chest.

There has been interest over the years in attempting to accelerate fistula closure with agents such as atropine, diamox and radiotherapy[2]. Somatostatin and its analogues have also been employed, and 13 of 16 patients showed fistula closure following intravenous somatostatin infusion at a rate of 250 μg/h[13,14]. Kingsnorth *et al.*[15] showed no such benefit when using somatostatin in six patients with enterocutaneous fistula, including one with a pancreatic fistula. Pederzoli *et al.*[16] showed a significant decrease in the time of fistula closure in eight patients with high output fistulae treated with somatostatin and total parenteral nutrition, compared with 18 treated with parenteral nutrition alone. Ahren *et al.*[17] published a case report demonstrating the use of the somatostatin analogue SMS 201-995 in closure of a pancreatic fistula. Following fistula closure, their patient developed a pseudocyst in the head of the pancreas which required ultrasonographically guided needle aspiration. This is a very similar experience to that of the patient in the present series. The role of somatostatin in treatment is still not clear, but it may yet prove to be useful[18].

The mortality rate in the present series (22 per cent) is consistent with that of the other reports and reflects the severity of the underlying disease process. Four of the five deaths were due to multiple organ failure following necrotizing pancreatitis while the fifth death followed a complication of paracentesis. Only one patient died as a result of a septic complication of the pancreatic fistula itself. Prompt recognition of the fistula, supportive therapy, active investigation by fistulography and/or ERCP and timely intervention will give the best results in the management of pancreatic fistulae.

In a consecutive surgical series of 70 patients with chronic calcifying pancreatitis, 18 presented with fixed stenosis of the terminal common bile duct. Nine patients presented with jaundice and two had a palpable gallbladder. The most relevant laboratory datum in the series was a persistently high serum alkaline phosphatase level. Long tapering of the terminal common bile duct was the characteristic radiological sign in 45 of our patients. In five of the 18 cases compression of the terminal bile duct was due to cephalic pseudocysts. Hepaticojejunostomy-en-Y was the type of drainage chosen in 16 cases, and an end-to-side technique was used in 15 patients. Side-to-side choledochoduodenostomy was performed in two cases. In 14 patients, biliary drainage was associated with other surgical procedures on the pancreatic parenchyma. No postoperative complications due to the biliary drainage occurred in this series.

Keywords: Chronic pancreatitis, chronic pancreatic cholangiopathy, hepaticojejunostomy

Fixed stenosis of the terminal common bile duct (or chronic pancreatic cholangiopathy) is a relatively frequent non-metabolic complication of chronic calcifying pancreatitis. Its importance lies in the fact that it can favour the onset of cholangitis or secondary biliary cirrhosis, cause diagnostic confusion with pancreatic neoplasm, and cause persistent pain after direct operations on the pancreatic parenchyma.

The incidence of biliary stenosis secondary to chronic pancreatitis has been extremely variable in different reported series[1,2], ranging from 4 per cent[3] to 46 per cent[4]. This ratio may vary according to whether studies are based on a clinical[5], surgical[6], radiological[4] or autopsy series[7]. The condition must be distinguished from the slight, transient, hyperbilirubinaemia which may occur in patients with clinical episodes of acute inflammation in the course of chronic pancreatitis. In these circumstances, oedema often subsides with resolution of the acute inflammatory process and specific therapy is not required unless a major complication develops[8].

Fixed stenosis of the lower common bile duct due to chronic pancreatitis should be suspected whenever high levels of serum alkaline phosphatase persist, regardless of whether they are accompanied by a high serum bilirubin level[9,10]. The next step in investigation is cholangiography, whether percutaneous or endoscopic, although preference is now given to the latter as it can also demonstrate alterations of the pancreatic ductal system. Even though diagnostic uncertainty between chronic pancreatitis and cancer of the head of the pancreas is not frequent in experienced centres, there are cases in which doubt may remain even after intraoperative biopsy, so that the best biopsy, in such instances, is the resection specimen[11]. Opinion is also divided about the optimal method of treatment of bile duct stenosis in chronic pancreatitis[12–15]; the role of the various drainage procedures is debated, and there are those who advocate the Whipple resection for this condition[16].

This paper relates our experience with pancreatic cholangiopathy and its surgical treatment in a consecutive series of patients undergoing surgery for chronic pancreatitis.

Patients and methods

From January 1975 to October 1987 we operated on 70 patients with chronic pancreatitis. Eighteen of these patients presented with a non-metabolic complication of chronic pancreatitis, namely stenosis of the terminal common bile duct. Of this subgroup, 17 patients had an alcoholic aetiology; in one patient the cause of chronic pancreatitis was not identified. Thus, 26 per cent of the patients with a confirmed diagnosis of chronic pancreatitis had persistent extrahepatic obstruction of the biliary tract. There were 15 men and three women ranging in age from 31 to 64 years (mean 38·2 years).

Nine patients were clinically jaundiced on admission to hospital. In two cases there was a palpable gallbladder and one patient experienced intermittent pyrexia. The most relevant laboratory datum was a persistently raised serum alkaline phosphatase level, averaging 522 units/l (normal value 92 units/l), in all the patients of this series.

Before operation the biliary system was evaluated in eight cases by endoscopic retrograde cholangiopancreatography and, in one non-jaundiced patient, by intravenous cholangiography. In the other nine patients, radiological diagnosis was achieved by intraoperative cholangiography (*Figure 1*). Extreme dilatation of the common hepatic duct was only demonstrated on two occasions, while in the other patients the duct was slightly dilated or had a normal diameter. The long tapering terminal common bile duct characteristic of this situation was seen in 15 of our patients, but other radiological presentations may appear (*Figure 2*), as in three of our 18 cases. In these three cases some doubt remained after the cholangiography about the differential diagnosis; however, the surgical biopsy confirmed the diagnosis of chronic calcifying pancreatitis rather than neoplasia.

In ten patients, bacteriological culture of the bile was obtained and revealed growth of *Escherichia coli* in four cases and *Proteus vulgaris* in one. In the other patients for whom bacteriological culture study was undertaken there was no growth.

In five of the 18 patients (28 per cent) compression of the terminal

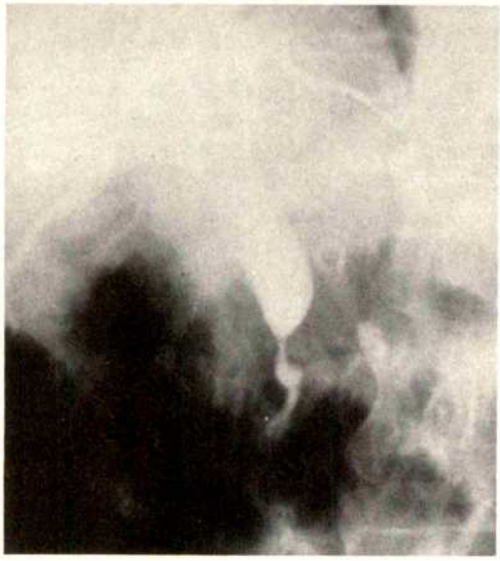

Figure 2 *An endoscopic retrograde cholangiopancreatogram demonstrating stenosis of the terminal bile duct and an irregular dilatation above the stenosis, caused by chronic pancreatitis*

common bile duct was due to the presence of pseudocysts in the head of the pancreas, and in the others it was considered to be due to calcification and/or fibrotic nodules caused by chronic pancreatitis. In 14 of the total group of 70 patients (and here we are including those with pseudocysts of the head of the pancreas, as well as those having biliary drainage) side-to-side pancreatojejunostomy was also performed (in 13 cases) and subtotal pancreatectomy (in one case). In three patients the biliary–digestive anastomosis was performed as an isolated procedure, while two of these patients had undergone pancreaticojejunostomy, 6 years previously in one case and 9 months earlier in another. Finally, one patient underwent biliary drainage without previous or concomitant pancreatic operation; he was jaundiced, with a serum alkaline phosphatase level four times the normal value, had pancreatic calcifications and was diabetic, but did not have painful chronic pancreatitis.

Hepaticojejunostomy using a Roux-en-Y loop was the type of drainage chosen in 16 cases; the anastomosis was end-to-side in 15 patients and side-to-side in one (due to technical difficulties in isolating the hepatic duct from the portal vein, secondary to the inflammatory process and associated portal hypertension). Side-to-side choledochoduodenostomy was performed in two cases in which the bile duct had thickened and dilated walls. In those patients who had not been submitted previously to cholecystectomy, the gallbladder was removed.

Results

There was no immediate postoperative complication attributable to the biliary drainage procedure in this group of patients. On follow-up (mean duration 3·2 years), 14 patients are alive at the time of this report; levels of serum alkaline phosphatase are slightly elevated in five patients (mean value 183 units/l) and are normal in the others. Of the surviving patients, 12 continue to abuse alcohol but have not shown clinical evidence of biliary obstruction. The long term mortality rate of 22 per cent (four of 18 patients) was attributable to progression of the underlying disease and not to the failure of the biliary–digestive anastomosis.

Discussion

The actual prevalence of chronic pancreatic cholangiopathy remains unknown, as series of patients with different types of pancreatitis are included in the same study. For example, the recent study of Stabile *et al.*[17] describes a prevalence of 4 per cent in 910 patients with chronic pancreatitis. On the other hand, it does not mention the method employed to diagnose pancreatitis, and there is no doubt that in many instances it is based on clinical rather than surgical diagnosis. The study of Aranha *et al.*[3] shows a similar prevalence to that reported by Stabile *et al.*, where cases with fixed stenosis of the terminal common bile duct were taken from a large series of patients with a clinical diagnosis of pancreatitis. The other extreme is a study of Wisloof *et al.*[4] where 46 per cent of the cases of chronic pancreatitis had stenosis of the terminal bile duct. Perhaps this high rate is due to the selection of patients, because it refers to a series with a radiological diagnosis of chronic pancreatitis.

In studies consisting mainly of surgical patients[6,8,15] admitted in order to treat severe pain or non-metabolic complications of chronic pancreatitis, the percentage of patients with pancreatic cholangiopathy would be higher than that reported by many authors[1,3,17,18]. This is probably due to the fact that these are patients with pancreatitis of sufficient severity to merit surgical treatment. Furthermore, chronic pancreatitis is a disease which can manifest itself in various ways in different places, despite a common aetiology[13,19–21].

Stenosis of the terminal common bile duct in chronic pancreatitis can bring about important hepatobiliary complications, such as cholangitis and secondary biliary cirrhosis. Warshaw *et al.*[22] demonstrated that waiting for evidence of advanced biliary disease to develop in patients with biliary stenosis due to pancreatitis increases the incidence of secondary biliary cirrhosis. On the other hand, Yadegar *et al.*[23] suggested that patients with high alkaline phosphatase levels and pancreatitis must be followed up with biannual liver biopsies to allow early detection of pathological changes suggestive of secondary biliary cirrhosis, so that surgery can be instituted. We believe that, in addition to the difficulties of effective biannual follow-up of patients with chronic pancreatitis, repeated biopsy of a cholestatic liver is not without risk.

When compression of the terminal common duct is due to a non-calcified inflammatory mass on radiological study, cancer of the pancreas must always be excluded. The experienced pancreatic surgeon may still have diagnostic doubts even when the clinical, laboratory, radiological and intraoperative findings are considered together. Every attempt should be made to obtain the definitive diagnosis during operation and the surgeon must be prepared to resect a mass in the head of the pancreas at the first operation if doubt persists, as secondary operations in this area make dissection dangerous and difficult. Even though the final pathological diagnosis proves to be chronic pancreatitis, the literature[16,24] suggests that duodenopancreatectomy is an effective operation because it decompresses the splenoportal system, relieves cholestasis and avoids any future duodenal obstruction. Furthermore, it resects the inflammatory mass in the head of the gland, which is considered by some to be the pacemaker of chronic pancreatitis[25]. It is important to emphasize that all pancreatic operations should be planned in advance and proper, informed consent obtained from the patient and the relatives[26].

In 28 per cent of the cases in the present series there was a pseudocyst in the head of pancreas which was drained into the loop used for pancreatojejunostomy. Yadegar *et al.*[23] present cases of such cysts with compression of the terminal bile duct and cholestatic syndrome, where cystenterostomy resulted in the disappearance of biliary obstruction. On the other hand, Machado *et al.*[6] report two patients in whom no biliary drainage was initially performed, but who later developed jaundice. It is well known that relief of the causative factor may allow the biliary obstruction to recede, and intraoperative cholangiography is recommended to verify the patency of the biliary tree after cystenteroanastomosis[23]. It has been our practice to perform a bilioenteric anastomosis using a Roux-en-Y loop in this situation if the preoperative clinical and laboratory data are consistent with cholestasis and if at operation there proves to be dilatation of the common hepatic duct. Even though some of these patients may not have fixed stenosis, we justify our procedure on the basis that the risk of not performing biliary drainage is certainly greater than that of prolonging the operation time.

Even though choledochoduodenostomy is the treatment of choice of a large number of authors[9,12,17,23,27] when faced with chronic pancreatic cholangiopathy, this operation has some drawbacks. To remain patent over a long period, the anastomotic diameter must be at least 1·5cm[28], and such ductal dilatation is not the rule in chronic pancreatic cholangiopathy. Choledochoduodenostomy performed with a thin-walled bile duct, as is common in this condition, can be complicated by leakage and duodenal fistula formation. Elliot[29] has described cases in which there was the need to revise a side-to-side choledochoduodenal anastomosis in patients who had food packed in the bile duct beneath the anastomosis. Although some authors consider that the 'sump syndrome' is more theoretical than real[17,30,31], they recommend performing this anastomosis in an end-to-side manner. On the other hand, the great advantage of this operation, as we see it, is the speed and ease of its performance when a side-to-side technique is used. If the surgeon has to dissect and separate the bile duct from the portal vein in order to perform an end-to-side anastomosis, the advantages discussed above are lost.

Another method of treatment of chronic pancreatic cholangiopathy is cholecystjejunostomy[13,15]. As these patients' life expectancy is long, cholecystenterostomy should be reserved for when there is particular technical difficulty, as when there is associated portal hypertension. This anastomosis really depends on the diameter of the cystic duct and not on the diameter of the anastomosis performed; death due to postoperative cholangitis has been reported[10]. Dayton *et al.*[32] suggest that the gallbladder as a route for biliary drainage should be reserved for terminal malignant disease, when the patient's life expectancy is short.

In the majority of our patients we performed end-to-side hepaticojejunostomy Roux-en-Y. This operation avoids the sump syndrome and does not involve the duodenum in the anastomosis, which can occasionally be obstructed or involved by the pancreatic inflammatory process. Although hepaticojejunostomy Roux-en-Y is said to increase the incidence of postoperative peptic ulcer[33–35], many publications do not support this contention[36–40]. We should not expect biliary-enteric drainage to relieve the painful symptoms of chronic pancreatitis, as the aim of these operations is to prevent cholangitis and secondary biliary cirrhosis and to treat cholestasis which follows compression of the terminal bile duct by an inflammatory pancreatic mass.

Post-transplantation pancreatitis is an infrequent complication with a high risk of mortality. In a 7-year period, there were five patients who had documented pancreatitis out of a total of 488 renal homograft recipients, an incidence of 1 per cent. Two cases occurred in patients with an orthotopic transplant, one of them as a result of surgical injury of the pancreas and the other as a consequence of cytomegalovirus infection. The third case was an acute pancreatitis of hypercalcaemic origin, the fourth patient developed postoperative pancreatitis and acute acalculous cholecystitis, and the fifth had acute pancreatitis and sepsis associated with cytomegalovirus infection. Three patients died as a direct result of the complication. The mean incidence and mean mortality rate of post-transplantation pancreatitis, as determined from our review of the literature of the last 15 years, are 2·3 and 61·3 per cent, respectively; these are similar to the figures found up to 1970 of 1·7 and 52·2 per cent. A multiplicity of factors present in the uraemic patient may be responsible for the continued frequency of post-transplant pancreatitis despite advances in surgical technique and immunosuppressive therapy.

Keywords: Renal transplantation, acute pancreatitis, hypercalcaemia, immunosuppressive therapy, cytomegalovirus infection

Acute pancreatitis is an infrequent but severe complication of renal transplantation. In a review of the literature up to 1970, there were 23 reported cases of pancreatitis with 12 deaths in 1321 renal allograft recipients, an incidence of 1·7 per cent and a mortality rate of 52 per cent[1]. These figures have not changed 15 years later; a recent survey documented an incidence of 2·3 per cent and a mortality rate of 61·3 per cent in 3253 renal transplantation recipients[1–15] (*Table 1*). These data highlight acute pancreatitis as an uncommon but often fatal complication in renal transplant recipients, despite recent advances in surgical technique and immunosuppressive therapy. A multiplicity of factors present in the uraemic patient may be responsible for the development of pancreatitis, which makes it difficult to identify the causative agent in most cases. We have diagnosed five instances of pancreatitis among 488 recipients of renal transplants in a 7-year period (1981–87).

Patients

Case 1

A 37-year-old man was diagnosed as having chronic renal failure secondary to membranoproliferative glomerulonephritis, which was confirmed by renal biopsy, in August 1975. In 1977, haemodialysis was instituted. A cadaver kidney was transplanted in April 1984 in an orthotopic position. Immunosuppression consisted of azathioprine and corticosteroids. Three intravenous prednisone pulses (200 mg each) were administered for rejection 12 days after transplantation. The patient complained of fever and left pleuritic chest pain 15 days after transplantation. Chest X-ray showed a small pleural effusion and ultrasonography revealed a left subphrenic collection. Antibiotic therapy was given and his condition improved. Clinical manifestations reappeared 30 days later and a second ultrasonograph disclosed a new subphrenic collection, 7 cm in diameter; needle aspiration produced 180 mm^3 of purulent fluid. The patient underwent surgical drainage of a small collection of pus in the lesser omentum and of a perirenal abscess. His clinical condition deteriorated 2 months later in spite of acceptable renal function. Computed tomographic (CT) scanning revealed a fluid collection in the lesser omentum. The patient was operated on and haemorrhagic necrotizing pancreatitis with a pancreatic abscess was found; the abscess was drained and a sample taken for histopathological examination. He remained septic and died on the fourth postoperative day. Pathological examination of the pancreatic biopsy showed the presence of acute haemorrhagic pancreatitis with cytomegalic inclusions (*Figure 1*).

Case 2

A 42-year-old woman was maintained on haemodialysis because of glomerular nephropathy from March 1975. In December 1983, she received a cadaveric renal allograft implanted in the right iliac fossa, but 30 days later the allograft was removed because of an irreversible episode of acute rejection. The patient received a living donor renal allograft on 23 January 1985 implanted in an orthotopic position. Immunosuppression consisted of cyclosporin and azathioprine. She complained of fever and left lumbar pain which radiated to the iliac fossa 12 days after transplantation. Ultrasonography disclosed a 200 mm^3 perinephric collection, which was evacuated under sonographic control. Analysis of the fluid showed an amylase and lipase content of 48 000 and 5200 units/l, respectively. Because of the persistence of clinical symptoms, a CT scan was performed which demonstrated recurrence of the perinephric collection. With the presumptive diagnosis of distal pancreatitis resulting from surgical injury, operation was undertaken and a peripancreatic collection was found (posterior to the body of the pancreas and close to the splenorenal anastomosis), with oedema and induration of the body and tail of the gland. The spleen was removed and a distal pancreatic resection performed. The postoperative course was uneventful and renal function remained stable. Histopathological examination of the surgical specimen showed inflammatory lesions compatible with acute pancreatitis. However, 16 months after surgery the patient was referred because of abdominal pain, fever and chills. Serum amylase and lipase levels were 529 and 379 units/l (normal value 200 units/l), respectively. A new episode of acute pancreatitis was diagnosed and supportive measures were instituted. Ultrasonography showed a cystic lesion in the body of the pancreas suggestive of a pancreatic pseudocyst. A cystogastrostomy was performed because of persistence of clinical symptoms and increased serum amylase and lipase levels. She developed an episode of gastrointestinal bleeding and died 30 days after operation.

Case 3

A 59-year-old man had undergone nephrectomy because of renal tuberculosis at the age of 29. Subsequently, stenosis of the bladder neck and recurrent pyelonephritis developed which caused progressive renal failure. In 1980, he was placed on haemodialysis. In August 1984 he received a living donor renal allograft which was implanted in the right iliac fossa and azathioprine and prednisone were administered. One month later, the left kidney was removed and he was treated with antituberculous medication (isoniazid and rifampicin). An increase in

serum levels of transaminase, γ-glutamyl transpeptidase, bilirubin and alkaline phosphatase were detected 15 days later, and all drugs except corticosteroids were discontinued. However, hepatic dysfunction associated with mild jaundice, pruritus, asthenia and weight loss persisted. Abdominal ultrasonography did not reveal dilatation of the intrahepatic biliary tree; liver biopsy disclosed cholestasis and hepatitis-like lesions. Tests for Australia antigen were negative, as were HBeAg and anti-HBe titres. The patient was discharged and maintained on corticosteroids. He was admitted again, 8 months after transplantation, because of ascites and mild encephalopathy. Renal function had remained stable. Physical examination revealed intense jaundice, ascites and grade I–II encephalopathy. Laboratory tests showed a serum bilirubin level of 16·7 mg/dl, serum glutamic oxaloacetic transaminase (SGOT) 630 units/l, serum glutamic pyruvic transaminase (SGPT) 410 units/l, alkaline phosphatase 530 units/l, γ-glutamyl transferase 157 units/l and Quick's test 55 per cent. Serum calcium levels were increased to 10·5–11·6 mg/dl. The patient was treated with cholestyramine resin, spironolactone and prednisone. Pain in the upper abdomen appeared suddenly 14 days after admission. Abdominal paracentesis obtained a clear non-infected transudate. The abdominal pain became worse, the general condition of the patient deteriorated, and dyspnoea and metabolic acidosis developed. Plain abdominal film showed dilatation of the transverse colon. Blood tests disclosed serum amylase levels of 1316 units/l, lipase 415 units/l, white blood cell count 19 600 mm^3 with 84 per cent segmented neutrophils and a serum calcium level of 16·8 mg/dl. In the ascitic fluid, the amylase level was 1119 units/l, the protein content 1 g/l, and the glucose content 66 mg/dl. The patient was transferred to the intensive care unit, but a few hours later, died of cardiorespiratory arrest and irreversible metabolic acidosis.

Case 4

A 53-year-old man, who had undergone left nephrectomy because of pyonephrosis in 1970, had been maintained on haemodialysis since May 1986 because of end-stage renal failure secondary to polycystic renal disease. In July 1987, he received a cadaveric renal allograft implanted in the left iliac fossa. Immunosuppression consisted of cyclosporin. The patient was reoperated on 24 h later because of a haemoperitoneum. Ascites developed in the immediate postoperative period. Laboratory data showed cholestasis with a serum direct bilirubin level of 9·7 mg/dl, total bilirubin 9·9 mg/dl, SGOT 33 units/l, SGPT 47 units/l, alkaline phosphatase 121 units/l, Quick's test 60 per cent and amylase 1930 units/l. Despite treatment with cyclosporin since transplantation, renal function deteriorated and haemodialysis was started 8 days later. Reduction of cyclosporin dosage resulted in normalization of serum creatinine. Abdominal ultrasonography, performed as a routine control examination, revealed an epigastric 15 × 9 cm collection which was drained under ultrasonographic control; 180 mm^3 of fluid were obtained. Culture of the fluid yielded growth of *Proteus mirabilis* and its amylase concentration was 30 000 units/l. The fluid collection persisted despite repeated punctures. In September 1987, the patient was operated on and acute acalculous cholecystitis and a pancreatic abscess were found. The abscess was drained and a cholecystectomy was performed. The patient had no postoperative complications and renal function remained stable.

Case 5

A 41-year-old woman was placed on haemodialysis because of end-stage renal failure secondary to chronic glomerulonephritis. She received a cadaveric renal transplant implanted in the right iliac fossa in March 1987. Immunosuppression consisted of azathioprine and corticosteroids. The patient complained of abdominal pain 32 days after transplantation. Blood tests showed increased serum amylase and lipase levels (460 and 234 units/l, respectively); 48 h later, the serum amylase concentration was 750 units/l, lipase was 191 units/l and the calcium level was 6·9 mg/dl. The diagnosis of acute pancreatitis was established and supportive measures were initiated. Abdominal ultrasonography showed the presence of peripancreatic fluid and parenchymal changes compatible with acute pancreatitis. The clinical condition progressively deteriorated, and blood tests disclosed an increase in cholestatic enzymes and decrease in the haematocrit. Fibreoptic endoscopy showed erosive oesophagitis and a duodenal ulcer. Consciousness was lost 18 days after the appearance of abdominal pain, as a result of encephalitis due to cytomegalovirus infection (elevated IgM-CMV antibody titres were detected). The patient died 3 days later of cardiorespiratory arrest. On autopsy, changes compatible with acute pancreatitis and sepsis due to cytomegalovirus infection were seen.

Discussion

In the present study, the incidence of post-transplantation pancreatitis was 1 per cent. However, three patients succumbed directly to this complication, a mortality rate of 60 per cent. In addition, one patient died 1 year after renal transplantation as a result of surgical treatment of a pancreatic pseudocyst that developed as a complication of the initial episode of acute pancreatitis; this results in an overall mortality rate of 80 per cent.

Table 2 details a series of factors that may contribute to pancreatitis in the complex setting of homotransplantation. Inflammatory changes in the pancreas have also been said to be very common in uraemia. Necropsy findings in cases of chronic renal failure have documented inflammatory pancreatic lesions in up to 52 per cent of patients who had not received immunosuppressive therapy or showed any clinical evidence of pancreatic disease[4,8,9,11,13,15].

The intensive immunosuppressive regimen used in renal transplant patients is a plausible explanation for post-transplantation pancreatitis[16]. Azathioprine can cause pancreatitis and rapid improvement has occurred after cessation of azathioprine with abrupt recurrence of pancreatic symptoms when treatment was reinitiated. Although several experimental studies have described corticosteroid-induced pancreatic changes (including pancreatic necrosis)[17], the relationship between steroids and pancreatitis is more difficult to establish clinically. Cyclosporin administration has not been associated with acute pancreatitis, although a direct toxic effect of this drug upon exocrine and endocrine pancreas has been observed[17–20].

The incidence of hyperparathyroidism is increased both in patients with renal transplants and in those with pancreatitis[21]. The question must be considered whether pancreatitis in patients with renal transplants is caused by increased levels of circulating parathormone or elevated serum calcium concentration[1,4,6–15]. In our third case, acute pancreatitis was certainly associated with high serum calcium levels.

That pancreatitis may be a form of 'rejection pancreatitis', in which the host forms an antibody reactive with pancreatic cellular surfaces, resulting in destruction of the pancreas, has been proposed. This possibility is supported by the evidence of signs of vasculitis in pancreatic biopsies from renal allografted patients[1,9–14].

Infection is a major cause of complications after renal transplantation and there is a well known relationship between pancreatitis and cytomegalovirus and herpesvirus. Conceivably, there could be direct colonization of the pancreas by such viruses[10]. Increased serum titres of anti-CMV antibodies as well as cytomegalic inclusions in the pancreas of renal transplant patients have been documented[22,23]. Elevated IgM-CMV antibody titres were found in two of our cases, as were cytomegalic inclusions.

Episodes of acute pancreatitis in renal allografted patients may also develop due to biliary tract disease and alcoholism, the commonest causes of pancreatitis in the non-uraemic population. It would seem prudent, in view of the known effects of alcohol abuse on the pancreas and the severity of the clinical disease in immunosuppressed patients, to screen potential recipients for a history of alcoholism and to proscribe alcohol following transplantation[12,13]. Although biliary tract disease is not the usual cause of acute pancreatitis in renal transplant patients, as the maximal age of patients undergoing renal transplantation has been rising steadily, ultrasound scans of the biliary tree are mandatory to exclude small calculi in cases of pancreatitis[12].

Miscellaneous causes of pancreatitis in postrenal transplant patients include uraemic hyperlipidaemia[24], hypertension[13], diabetes[15], administration of drugs (particularly thiazides)[8,9,11] and surgical pancreatic injury. Pancreatic injuries may occur during left nephrectomy and associated revascularization of the graft with the splenic vessels of the recipient. The technique of orthotopic renal transplantation uses the retroperitoneal approach to the splenic hilus via the lumbar region. The greatest danger in this approach is the possibility of damaging the pancreas when the renal and splenic vessels are dissected. However, of the total 132 orthotopic transplants performed in our institution, only the cases reported here (cases 1 and 2) had post-transplantation pancreatitis. These factors probably play minor roles in the overall postrenal transplantation population but each, together or in combination, may be significant for an individual patient.

The diagnosis of pancreatitis depends greatly upon an increase in the serum amylase level. When renal insufficiency occurs, evaluation of the serum amylase level can be difficult, as most patients with poor renal function have hyperamylasaemia. However, in renal failure, the amylase level is rarely greater than twice normal. The ratio of amylase clearance to creatinine clearance as determined on a random urine specimen or diagnostic paracentesis may be of great value in the diagnosis of patients who are suspected of having post-transplantation pancreatitis. Also, ultrasonography and CT scan deserve wide use in the diagnosis of pancreatitis. Even with good antibiotic cover, endoscopic retrograde cholangiopancreatography can be dangerous in cases of acute or recurrent acute pancreatitis, and an abscess may develop. Intensive medical management with particular attention to volume replacement and electrolyte balance is essential in the management of these patients. Early surgery has been advocated by some but the role of surgery in these very ill patients has yet to be defined and the risks of operation are extremely high. However, in cases of necrotizing pancreatitis, early operation may lead to increased survival. The difficulty here is to identify certain prognostic features that will select the high-risk patient who will benefit from early operation. Also, surgery is indicated if there is evidence of surgical injury of the tail of the pancreas, pancreatic abscess formation, or the development of a non-resolving pseudocyst.

One hundred and sixty-four patients operated on for calculus disease of the common bile duct during the period 1977–85 were followed in a special clinic; the attendance for follow-up at 1, 3, 5 and 7 years was 90, 74, 60 and 54 per cent respectively. Eleven patients died during the study period (6·7 per cent), none of the deaths being attributable to biliary tract disease. The overall incidence of retained calculus was 2·4 per cent (four patients), but no cases of retained calculi were recorded in the last 4 years of the study; in this period, with the advent of choledochoscopy and fluoroscopic cholangiography, the incidence of the supraduodenal compared with the transduodenal approach to the common bile duct increased significantly ($P<0·001$). *Twenty-two of 56 patients (39 per cent) followed up for 5 years remained or became symptomatic after surgery, the majority of whom had underlying conditions unrelated to disease of the biliary or pancreatic tree. This specific follow-up clinic has been of value in the long-term audit of patients undergoing bile duct surgery for choledocholithiasis and it has verified that a change of policy from transduodenal to supraduodenal choledochotomy with preservation of the sphincter, and use of the choledochoscope and fluorocholangiography, produce better results.*

Keywords: Choledocholithiasis, choledochotomy, transduodenal sphincterotomy

The operative risks and the incidence of recurrent disease after surgery for calculus disease of the biliary tract are well documented and are based primarily on retrospective studies[1–7]. Many patients remain symptomatic despite no demonstrable evidence of recurrent disease[8,9], and apart from experimental studies[10] little is known about liver function as assessed by routine tests after biliary tract surgery. This prospective study of 164 patients, all of whom had undergone surgery for calculus disease of the common bile duct, aims to assess and correlate clinical outcome with serial postoperative liver function tests, knowing the operative findings and procedures.

Patients and methods

During the study period from January 1977 to December 1985, 164 consecutive patients (121 women, 43 men) who had undergone surgery for calculus disease of the common bile duct were referred to a designated biliary follow-up clinic. Patients' ages ranged from 19 to 94 years (mean age 59·4 years). Symptoms were recorded and serum bilirubin, alkaline phosphatase and glutamic oxaloacetic transaminase (SGOT) levels were determined. Patients were reviewed 6 months after their operation and if clinical examination and laboratory investigations were normal they were seen annually thereafter.

The operative procedures performed included supraduodenal choledochotomy (56), transduodenal sphincteroplasty (81), combined supraduodenal and transduodenal approach (11), and choledochoduodenostomy (16). *Table 1* compares the pattern of surgical approach to common bile duct calculi in the early (1977–81) and later (1981–85) parts of the study period. There was a significant reduction in the number of transduodenal compared with supraduodenal explorations ($P<0·001$). This coincided with the introduction of routine choledochoscopy and fluoroscopic cholangiography.

Fifty-three patients (32.3 per cent) had been jaundiced on initial presentation before surgery (serum bilirubin >17 μmol/l). Eighty-five (51·8 per cent) had elevated alkaline phosphatase levels (>100 units/l) and 59 (35·9 per cent) had elevated SGOT levels (>40 units/l) before operation. All patients with elevated concentrations of serum bilirubin or SGOT had an associate high alkaline phosphatase level.

Attendance for follow-up at 1, 3, 5 and 7 years was 90, 74, 60 and 54 per cent respectively. Five-year follow-up data were available for 56 of 94 patients operated on during the period 1977–81. seven patients died within 5 years of surgery, three failed to attend for any follow-up, and six were elderly (>70 years) but symptom-free at first review and follow-up by the general practitioner was thought to be more appropriate. The remaining 22 patients attended initially but for varying periods of time: one review only (four patients), two reviews (two patients), three reviews (nine patients) and four reviews (seven patients). All 22 patients were symptom-free and had normal liver function tests at last review.

Results

An 86-year-old woman died on the 12th postoperative day owing to biliary peritonitis following removal of a T tube. There were no other postoperative deaths. Eleven patients died during the study period (6·7 per cent), none of the deaths being attributable to disease of the biliary tract. The causes of death were myocardial infarction (four), cerebrovascular accident (three), gastrointestinal carcinoma (three) and bronchopneumonia (one).

Of the 56 patients with 5-year follow-up, 22 remained or became symptomatic (39 per cent). Eight patients developed complications related to common bile duct surgery (14 per cent). Residual calculi are known to have occurred in four patients in the series (2·4 per cent): all presented within 12 months of surgery and no instances of retained calculi have

been recorded since 1981. Three of the four cases followed supraduodenal choledochotomy and were removed at 6 weeks, 2 months and 4 months by heparin lavage via a T tube, by choledochoduodenostomy, and by transduodenal sphincteroplasty, respectively, the latter two after attempted endoscopic sphincterotomy. One case followed transduodenal sphincteroplasty and was removed endoscopically 10 months after operation; this patient later developed cholangitis and chronic pancreatitis and requires regular analgesia. Two other patients also developed cholangitis at least 6 months after transduodenal sphincteroplasty, one in association with septicaemia while the second subsequently developed pancreatitis with an associated pseudocyst. One patient developed obstructive jaundice following transduodenal sphincteroplasty, and this was found to be due to vegetable matter in the lower common bile duct. Another patient developed a common hepatic duct stricture, presumably related either to the cholecystectomy performed at the same time as transduodenal sphincteroplasty or to persistence of the initial narrowing related to the gallbladder empyema (Mirizzi's syndrome); this patient, to date, has responded to long-term antibiotics. Delayed complications related to surgery occurred in five of 63 patients who had undergone transduodenal sphincteroplasty compared with three of 18 patients who had undergone supraduodenal choledochotomy (not significant).

Ten of the 56 patients (18 per cent) developed pathology unrelated to biliary tract surgery which has responded to medical treatment. Liver function tests performed at the time of symptoms in these ten patients were normal (reflux oesophagitis, four patients; duodenal ulceration, two patients; diverticular disease, two patients; irritable bowel syndrome, one patient; pancreas divisum, one patient), and they were normal in the remaining four patients (7 per cent) who had symptoms but in whom investigations have revealed no underlying pathology.

Five patients who remained symptom-free after their operation had marginally elevated serum alkaline phosphatase levels at 5-year follow-up (mean 134 units/l, range 103–185 units/l). One patient had undergone removal of a retained calculus 6 weeks after supraduodenal choledochotomy. No obvious cause for the marginally elevated concentration of enzymes was found in the remaining four patients (transduodenal sphincteroplasty, three patients; choledochoduodenostomy, one patient).

Analysis of follow-up liver function tests in patients whose preoperative liver function tests were normal ($n=79$) revealed that at 6-month follow-up elevated levels of serum alkaline phosphatase occurred in 11 of 40 patients undergoing transduodenal sphincteroplasty (28 per cent) but did not occur in any of 26 patients who underwent supraduodenal choledochotomy ($P<0.005$, Fisher's exact test). At 5-year follow-up serum alkaline phosphatase had returned to normal concentrations in all but two of these patients. Analysis of follow-up liver function tests in patients whose tests were abnormal before surgery ($n=85$) showed no significant difference in the proportion with abnormal tests 6 months after transduodenal sphincteroplasty (16 of 41 patients, 39 per cent) compared with supraduodenal choledochotomy (13 of 30 patients, 43 per cent).

Discussion

Although there are a number of carefully reported retrospective studies documenting long-term clinical outcome after surgery for calculus disease of the common bile duct[1–6], prospective follow-up data are notably lacking[7]. Annual clinical assessment, serial liver function tests and further investigations, where indicated, have enabled us to provide detailed prospective data concerning long-term clinical and biochemical outcome after common bile duct surgery for benign disease. Ros and Zambon[9] have recently shown that a large proportion of patients remain symptomatic after simple cholecystectomy – many due to other gastrointestinal tract conditions. This study demonstrates that a large proportion of patients (39 per cent) also remain symptomatic after surgery for common bile duct stones and that many of these are likewise suffering from other gastrointestinal tract diseases.

The late mortality rate during the study period was high (6·7 per cent) but the majority of deaths occurred in the older age groups (mean age 78·1 years) and were chiefly due to degenerative arterial disease; this finding is similar to that reported by McSherry and Glenn[11] in a series of 11 808 consecutive patients operated on for non-malignant biliary tract disease.

The overall incidence of retained calculus (2·4 per cent) compared favourably with other series[4–6,12]. In our experience, the introduction of routine fluoroscopic postexploratory cholangiography and subsequently rigid choledochoscopy reduced the incidence of retained calculus and, apart from retained calculus, the procedure of supraduodenal choledochotomy[13] was associated with notably few long-term complications The transduodenal route is a technically more difficult approach and, although no postoperative deaths occurred in this series due to the procedure, transduodenal sphincteroplasty has been reputed to be associated with higher postoperative morbidity and mortality[1,4,6]. Furthermore, in our experience delayed cholangitis occurred in three of 81 patients following transduodenal sphincteroplasty and, although temporary, the procedure was also associated with a significantly higher incidence of elevated liver function tests 6 months after surgery in patients whose preoperative liver function tests were normal. These factors, together with the knowledge that a back-up endoscopic sphincterotomy service is readily available in the event of retained calculus, have resulted in a preference for a supraduodenal approach to the common bile duct except in circumstances such as the presence of multiple calculi in a non-dilated duct, a stone impacted at the papilla, re-exploration for a stone in the event of failed endoscopic retrograde cholangiopancreatography and sphincterotomy, or a short terminal common bile duct stricture with choledocholithiasis.

Transduodenal sphincteroplasty results in duodenobiliary reflux in some patients but it has been considered that reflux, provided it is combined with free egress from the biliary tree, is harmless. The increased incidence of transiently elevated liver function tests following transduodenal sphincteroplasty in this study, together with the pattern of long-term complications (cholangitis in three patients, two of whom also developed pancreatitis), raises the possibility that reflux of duodenal contents into the biliary tree may not be entirely harmless and suggests that patients who undergo transduodenal sphincteroplasty in particular should be reviewed regularly in the early postoperative period. Given that they are aware of the potential complications of such operative procedures, it would seem that follow-up by family practitioners is adequate and that a specific biliary follow-up clinic provides no significant benefit to individual patients in terms of long-term patient outcome.

A new classification of patients with Mirizzi syndrome and cholecystobiliary fistula is presented. Type I lesions are those with external compression of the common bile duct. In type II lesions a cholecystobiliary fistula is present with erosion of less than one-third of the circumference of the bile duct. In type III lesions the fistula involves up to two-thirds of the duct circumference and in type IV lesions there is complete destruction of the bile duct. A total of 219 patients were identified with these lesions from 17 395 patients with benign biliary tract diseases undergoing surgery. The incidence of type I lesions was 11 per cent, type II 41 per cent, type III 44 per cent and type IV 4 per cent. The majority had obstructive jaundice. In type I lesions, cholecystectomy plus choledochostomy is effective. In type II lesions, suture of the fistula with absorbable material or choledochoplasty with the remnant of gallbladder can be performed. In type III lesions suture is not indicated and choledochoplasty is recommended. In type IV lesions, bilioenteric anastomosis is preferred. Operative mortality rate increases according to the severity of the lesion, as does postoperative morbidity. During cholecystectomy, partial resection is recommended in order to extract the stones, visualize the common bile duct and define the type and location of the fistula. T tubes should be placed distal to the fistula.

Keywords: Cholecystobiliary fistula, Mirizzi syndrome, surgery

Mirizzi[1] originally described the syndrome that bears his name in 1948, when he found the following features in patients with gallstones: anatomical variation of a parallel cystic duct; gallstones impacted at the neck of the gallbladder or in the cystic duct; partial obstruction of the common bile duct secondary to compression by the stone or surrounding inflammation; recurrent cholangitis; and spasm of the circular muscular fibres in the hepatic duct Since his description, several isolated cases have been reported[2–11]. Communication between the gallbladder or cystic duct and the common bile duct is rarely referred to in the surgical literature[12–20]. After dealing with a number of patients with Mirizzi syndrome and cholecystobiliary fistula, we have come to realize that these are stages in the evolution of the same pathological condition.

The purpose of the present study is to define the incidence of the Mirizzi syndrome and cholecystobiliary fistula in a series of patients with gallstones, to propose a new unifying classification that includes both of these conditions, and to establish the surgical treatment for each stage of the pathological process.

Patients and methods

The present paper is a combination of a retrospective analysis (1976–82) and a prospective study (1983–87) of all patients operated on for gallstones in the Department of Surgery, University of Chile. A total of 17 395 patients were operated on during the entire period, so that approximately 1449 patients per year were submitted to cholecystectomy From this patient population, 219 patients (1 3 per cent) were considered to have Mirizzi syndrome and/or a cholecystobiliary fistula (see below).

A special procotol was designed for the study, in which 60 different parameters were included All data from each patient were documented on a chart and at the end of the study (July 1987), they were analysed by the IBM computer of the Faculty of Medicine (P240 IBM)

Pathological analysis

Each resected gallbladder was carefully examined histologically to exclude carcinoma All patients with benign strictures, stenosis of the sphincter of Oddi, carcinoma of the common bile duct and biliary–digestive fistulae were excluded from consideration Chronic cholecystitis corresponded to the presence of a gallbladder with a firm thick wall, and fibrosis. Histologically Aschoff–Rokitansky sinuses and mononuclear inflammatory cells were present. Acute cholecystitis corresponded to a gallbladder with fibrinous, shaggy, dull exudates with muscular engorgement with oedema and hyperaemia of the wall Histologically the presence of polymorphonuclear leucocytes was observed.

Acute suppurative cholangitis was defined during surgery as the presence of muddy bile or pus in the common bile duct, instead of clear green bile.

Definitions

For the present study, we have defined four evolving stages of the same disease and have classified them as follows (*Figure 1*):

1 *Type I lesion* external compression of the common bile duct due to a stone impacted at the neck of the gallbladder or at the cystic duct (i.e. the original Mirizzi syndrome)
2. *Type II lesion* presence of a cholecystobiliary fistula (cholecystohepatic or cholecystocholedochal) due to erosion of the anterior or lateral wall of the common bile duct by impacted stones, the fistula involving less than one-third of the circumference of the common bile duct
3. *Type III lesion* presence of a cholecystobiliary fistula with erosion of the wall of the common bile duct that involves up to two-thirds of its circumference
4. *Type IV lesion* presence of a cholecystobiliary fistula with complete destruction of the entire wall of the common bile duct

To determine the late results of treatment, a special questionnaire was completed with reference to pain, jaundice, loss of weight, tolerance to food, and whether the patient was content with the surgical result A total of 167 (76 3 per cent) of cases were followed in this way with a mean follow-up of 5 7 years (range 1–13 years)

For statistical evaluation, analysis of variance was used and $P<0.05$ was considered as statistically significant

Results

Among the 219 patients, 23 (10·5 per cent) had a type I lesion, 90 (41·1 per cent) a type II lesion, 97 (44·3 per cent) a type III

Fever present for previous 5 days (%)	70	57	67	67
Rectal temperature >38°C (%)	35	33	53	34

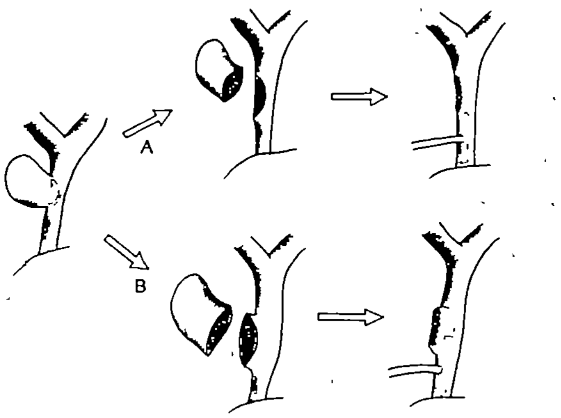

Figure 2 *Surgical alternatives for the repair of the common bile duct in patients with type II lesions Option A involves the simple suture, and in option B the cuff of gallbladder is used for choledochoplasty*

lesion and 9 (4·1 per cent) a type IV lesion. The main clinical findings in all cases are shown in *Table 1*. There was an increasing mean age in patients with type III and IV lesions. Almost all cases with type I, II and III lesions had a typical clinical picture of obstructive jaundice, but this was present in only six of the nine cases with type IV lesions

Previous oral cholecystography had been performed in 37 patients, showing no gallbladder filling in any patient. Ultrasonography was performed in 67 cases, demonstrating gallstones in all and a dilated proximal common bile duct in 54 of the cases. A type I lesion was suspected in six cases and a biliobiliary fistula in 12 patients

The main surgical findings in the gallbladder in the 219 cases are demonstrated in *Table 2*. Acute cholecystitis was more frequent in type I lesions, with multiple gallstones in approximately two-thirds of the cases. Chronic cholecystitis was frequently observed in patients with type II, III and IV lesions. The cystic duct was absent in all patients with type IV lesions and in two-thirds of patients with type II and III lesions. Stones were absent from the common bile duct in 92 per cent of cases with type I lesions and from 56 per cent of those with type IV lesions. In some patients with type II, III, and IV lesions, intrahepatic stones were also present. Acute suppurative cholangitis was more common in patients with type IV lesions.

Cholecystectomy was performed in all 219 patients, but was frequently partial or incomplete in patients with type II and III lesions, when a remnant of gallbladder was left in order to perform a choledochoplasty (*Table 3*). The surgical treatment in patients with type II lesions was most often suture closure (*Figure 2*) of the fistula (chromic catcut 4-0 or Vicryl® (Ethicon Ltd., Edinburgh, UK) 3-0) leaving a T tube distal to the closure for at least 2 months. In a quarter of type II patients choledochoplasty was performed, especially when the fistula was large. The most frequent method of repair of the fistula in type III lesions was also choledochoplasty using the cuff remnant of the gallbladder. The surgical treatment of patients with type IV lesions consisted of an end-to-end repair in five cases, a biliary enteric anastomosis in three, and a double hepaticostomy in one case.

The size of the cholecystobiliary fistula is shown in *Table 4*. Most patients with type II lesions had a fistula $\leqslant 10$ mm in diameter while, in patients with type III and IV lesions, the fistula was often larger.

Postoperative course is shown in *Table 5*. There was an increasing mortality rate, which was significantly greater when patients with type III and IV lesions were compared with other groups ($P < 0{\cdot}02$). The late results in the 204 patients discharged from the hospital are shown in *Table 6*. Two patients with type

I lesions developed a benign stricture 3 and 4 months after surgery, and underwent hepaticojejunostomy with good results. In patients with type II and III lesions, 4 per cent developed a benign stricture within a mean interval of 12 months after surgery. All patients with type IV lesions, as well as the patient with a type III lesion in whom end-to-end repair was performed, developed a benign stricture 4 months after surgery; hepaticojejunostomy was performed in all cases with a good clinical outcome to date.

Discussion

The Mirizzi syndrome as originally described consisted of the combination of a stone impacted at the neck of the gallbladder or cystic duct and a functional disorder of a putative sphincter within the common hepatic duct, but without any lesion of the common bile duct[1]. Mirizzi postulated that a number of factors might trigger or predispose to contraction of this 'sphincter', such as inflammation, aberrant vessels or stones impacted in the cystic duct. External obstruction of the bile duct following impaction of a stone in the cystic duct with associated inflammation was described by Kehr in 1905 and by Ruge in 1908 as a rare form of obstructive jaundice[14]. It is now well known that there is no sphincter within the hepatic duct, and the jaundice seen in these patients is due to external compression secondary to impaction of a stone at the neck of the gallbladder or cystic duct. Mirizzi described seven cases with this syndrome drawn from 4000 patients operated on for gallstone disease[21]. Dietrich, cited in References 2, 10 and 11, reported in 1963 that a parallel cystic duct was present in 18 per cent of patients with gallstones studied by operative cholangiography. However, this was observed in only 1·8 per cent of 5800 patients studied by Puente[22] in our country.

Treatment of the Mirizzi syndrome is based only on the removal of the initiating factors, namely the inflamed gallbladder, cystic duct and impacted stone. The common bile duct should be visualized and explored, if necessary, to exclude other causes of obstructive jaundice. Most inflammatory strictures will return to normal when the inflammatory process resolves, as occurred in 16 of our 18 followed cases with type I lesions. T-tube insertion will ensure biliary flow and decompression during the healing process. We agree with Lubbers[2]

Table 5 *Postoperative course in patients with external compression of the common bile duct or cholecystobiliary fistula*

that the term Mirizzi syndrome could now be abandoned, as it is only the first stage of a more complex process, as has been shown in our study.

Cholecystobiliary fistula is a rare entity Puestow[18] described it for the first time in 1942, when he published details of one case in 16 patients with spontaneous internal biliary fistulae. Later, Behrend and Cullen[14] described it as a separate entity in three patients with cholecystocholedochal fistula. Mirizzi[16] described four cases in 1954 and others have published descriptions subsequently[23,24]. Some authors in our country have described this type of biliary fistula in 0·1–0·5 per cent of all patients submitted to surgery for gallstones[11,12]. Corlette and Bismuth[19] have presented 24 cases treated in a 15-year period and propose a classification based on whether patients have a cystic duct. In our experience the majority of patients did not have a cystic duct and so this classification has little use in surgical practice.

It is important to establish the diagnosis of fistula before operation, in order to plan the surgical procedure. In our prospective study, which began in 1983, ultrasound proved very useful in this regard and we doubt whether CT scanning will be of more value. Preoperative cholangiography is valuable and we have used mainly the percutaneous transhepatic route because endoscopic retrograde cholangiopancreatography (ERCP) has become available only recently. However, in addition to preoperative diagnosis, ERCP also allows drainage to relieve cholangitis and may well improve the eventual surgical results[25–27].

We consider that the so-called Mirizzi syndrome and cholecystobiliary fistula are different evolving stages of the same disease process In patients with stones impacted at the neck of the gallbladder or cystic duct, repeated attacks of acute inflammation produce first distension of the gallbladder and then inflammation and thickening of the involved structures in the area. The distended and inflamed gallbladder comes to lie in close proximity to the common hepatic or common bile duct, and adhesion between the walls of the two structures with compression of the bile duct may produce obstructive jaundice and the type I lesion. The impacted stone may then cause pressure necrosis and further acute inflammation. In time the stone may erode through into the adjacent bile duct, producing the type II lesion or cholecystobiliary fistula The cystic duct becomes obliterated and disappears in the majority of cases, and this fact may create an even larger fistula, with destruction of the anterior wall of the bile duct (type III lesion). As time passes, the stone can slowly migrate into the bile duct, producing a complete necrosis of the duct (type IV lesion). Other internal biliary fistula (cholecystoduodenal, cholecystocolonic or cholecystogastric) have entirely the same mechanism of formation, but they do not form type I lesions as they communicate with organs with a greater lumen than the bile duct.

The practical importance of our new classification is that we propose different procedures according to the stage reached. At operation, it is always important to proceed with great care. Palpation of the impacted stone can give the impression of the presence of external compression of the common bile duct. We prefer to open the gallbladder, extract the stone(s) and visualize the interior of the gallbladder or the common bile duct. An operative cholangiogram should be performed to confirm the diagnosis, determine the location and size of any fistula, detect ductal stones and establish whether there is loss of integrity of the bile duct wall. In none of our cases was a mural defect created accidentally by over-enthusiastic cholecystectomy, a procedure that can produce a large fistula if care is not taken. Partial cholecystectomy helps to define more precisely the extension of any defect[28–30]. If the fistula is small and has eroded less than one-third of the circumference of the common bile duct, the defect can be sutured with fine absorbable sutures and a T tube placed distal to the fistula for 1 or 2 months. If the defect is larger, a cuff of gallbladder is used for fistula closure and a T tube is placed distally. We try never to place the T tube through the fistula, because leakage of bile occurs readily and a benign stricture can appear late after surgery. In some patients who present with stricture of the common bile duct due to this fistula, immediate hepaticojejunostomy may give good late results. End-to-end bile duct anastomosis is inadvisable; all of our six patients in whom we performed this procedure developed a benign stricture early after operation, necessitating hepaticojejunostomy. We therefore insist on preserving a cuff of gallbladder on the bile duct so as to use it in reconstruction. The greatest challenge is posed by the type IV lesions. Complete section of the common hepatic duct may be present and in one of our patients the lesion involved both right and left hepatic ducts. In such cases, we suggest immediate bilioenteric anastomosis or hepaticostomy, leaving a stent or a double T tube in place for a long period. It has been shown in animal experiments as well as in patients[30] that autoreconstruction of the common hepatic duct can occur if a viable longitudinal string of duct is left in continuity. However, we must stress that our follow-up may be too short to assess such cases and that benign stricture can lead insidiously to secondary biliary cirrhosis.

Wound sepsis following Ramstedt pyloromyotomy

N. Rao and
G. G. Youngson

Department of Surgery, Royal Aberdeen Children's Hospital, Cornhill Road, Aberdeen, UK
Correspondence to:
Mr G G. Youngson

Wound sepsis is common following pyloromyotomy in children and in a retrospective study of 178 cases the incidence of wound infection was 21 (11·8 per cent). On preliminary analysis, three variables were associated with wound sepsis: age, duration of projectile vomiting and surgical technique. Only surgical technique was found to be statistically significant on sequential multivariate analysis. Mass closure with polydioxanone was associated with a 1 per cent (one of 70) wound sepsis rate. Wound sepsis after pyloromyotomy is dependent on technique, and mass closure with polydioxanone is recommended. The routine use of tension sutures should be abandoned.

Keywords: Pyloromyotomy, wound sepsis, wound closure

Wound sepsis following pyloromyotomy remains a problem with the incidence varying from 0·3 to 14 per cent[1–4]. Immune deficiency, poor nutritional state[1,2] and proximity to the umbilicus[3] have been incriminated, but specific risk factors have not been identified. This study analyses the significance of 14 risk factors for wound sepsis.

Patients and methods

The case records of 192 consecutive pyloromyotomies performed over a 5-year period (1982–86) were reviewed and information on 14 variables collected (*Table 1*) Fourteen patients were excluded, 13 of these had been exposed to antibiotics either in the immediate preoperative period or at the time of surgery, and the medical record was unobtainable in one. Therefore 178 cases formed the study group

In-hospital wound sepsis was diagnosed in the presence of purulent discharge from the operative wound with or without a confirmatory microbiology report.

Operative technique comprised a right upper quadrant incision with rectus transection. Three methods of wound closure were assessed; (A) layered closure with Dexon® (Davis and Geck, Gosport, UK), (B) mass closure with polydioxanone and (C) layered closure with Prolene® (Ethicon Ltd., Edinburgh, UK) to the posterior sheath and catgut to the anterior sheath Nylon 'tension' sutures were used in both techniques A and C.

Skin closure included the use of Dexon, Vicryl® (Ethicon Ltd.) and catgut as subcuticular sutures and Prolene, Ethilon® (Ethicon Ltd) and Nurolon® (Ethicon Ltd.) as interrupted skin sutures. The method of closure was chosen according to the surgeon's preference.

General anaesthesia was used throughout with either suxamethonium, tubocurarine chloride (Duncan Flockhart and Company Ltd , Greenford, UK) or both, or fentanyl as muscle relaxant. Awake intubation was routine and inhalational anaesthetic agents were halothane or isoflurane with nitrous oxide Thiopentone was used in four cases. The period of postoperative nasogastric suction was 24 h.

Statistical method

Non-parametric statistical analyses were performed with the Mann–Whitney U test, and the χ^2 test (with Yates' correction when necessary) was used for comparison of groups of qualitative variables. Factors identified as statistically significant were included in a multiple logistic regression model to assess the simultaneous influence of these variables.

Results

There were 21 (11·8 per cent) wound infections and no wound dehiscences in the 178 cases. Fourteen patients (7·9 per cent) developed minor wound problems, induration with/without erythema, and were categorized as non-infected.

Staphylococcus aureus was cultured from 80 per cent of infected wounds and *Escherichia coli*, *S. albus* and *Proteus mirabilis*, alone or in combination, from the remaining 20 per cent. There were no deaths.

Details of the analysis of the factors that are not related to technique are given in *Tables 2* and *3*. The median age of infants who developed wound sepsis was significantly less (29 days, range 17–64 days) than that of non-infected infants (35 days, range 14–129 days). The duration of projectile vomiting was also significantly different between the two groups, wound sepsis cases vomiting longer (5 days, range 1–7 days) than non-infected cases (3 days, range 1–10 days). The influence of the technique of abdominal wall closure on wound sepsis is shown in *Table 4*. Tension sutures were used in 104 cases, 20 of whom developed wound sepsis (19·2 per cent) compared with one wound infection in cases without tension sutures ($\chi^2 = 11{\cdot}62$, $P < 0{\cdot}001$).

Age (days)	29	(17–64)	35	(14–129)	0·01*
Projectile vomiting (days)	5	(1–7)	3	(1–10)	0·005*

Figures given are the median value and range (in brackets). The Mann–Whitney U test has been used for the analysis. *$P < 0{\cdot}05$ indicates statistical significance

0007-1323/89/1144-03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Of 133 wounds closed with subcuticular skin sutures, 14 (10·5 per cent) developed wound sepsis compared with seven (16 per cent) of 45 wounds closed with interrupted non-absorbable sutures. This difference was not significant ($\chi^2 = 0{\cdot}817$, $P > 0{\cdot}5$).

The rank of the operator did not influence the wound sepsis rate (*Table 5*).

Multivariate analysis

Age, duration of projectile vomiting, and technique-related variables (technique A and C *versus* B and subcuticular skin closure *versus* interrupted non-absorbable sutures) were included in a multiple logistic regression model in the first stage of the multivariate analysis. Three variables were entered (age, duration of projectile vomiting and technique A and C *versus B*). Age and duration of vomiting failed to reach statistical significance. Closure technique remained highly significant ($P = 0{\cdot}002$). In the second stage, skin closure technique was introduced and this failed to reach statistical significance. Closure technique continued to remain statistically significant ($P = 0{\cdot}0052$).

Table 3 *Analysis of non-technical variables*

	n	Wound sepsis	%

Discussion

The incidence of wound infection following Ramstedt's pyloromyotomy in this study is comparable with wound sepsis rates of 9–14 per cent in other studies[1,2,5–7]. Wound sepsis rates are high in paediatric surgery, ranging from 46·5 per cent in infants to 11·6 per cent in children aged 5 years and over[3]. These high rates contrast markedly with rates of 0·3–4 per cent after Ramstedt's pyloromyotomy reported from North American[4,8–11] and two UK[12,13] series.

The reasons for the differing sepsis rates are not clear and indeed the factors influencing the development of wound sepsis remain ill-defined; immunological and nutritional causes[1,2] as well as proximity to the umbilicus[3] have been incriminated. This study shows that significant factors unrelated to technique include the age of the child and the duration of projectile vomiting before surgery; this implies a compromised nutritional and possibly immunological status not reflected in the body mass.

Before the routine introduction of tension sutures in Aberdeen, layered closure alone was used but was associated with a wound dehiscence rate of 3 per cent[14]. The use of tension sutures was abandoned in favour of mass closure with continuous absorbable monofilament suture (polydioxanone) by one of us (G.G.Y.) in 1984, but continues as the method of choice of some surgeons. We have had no cases of wound dehiscence in the last 5 years either with or without tension sutures and we now believe that tension sutures are not essential in preventing dehiscence. Mass closure with polydioxanone appears effective in preventing dehiscence and in addition is associated with a significantly lower wound infection rate. The use of monofilament absorbable suture material in mass closure has many theoretical attractions as the preferred method of closure in infancy[15]. Although we acknowledge that the development of technique B at the midpoint of the study introduces the possibility of a concurrent artefactual effect, the operative and perioperative management of the entire group remained otherwise entirely consistent, leaving change in technique as the factor contributing to differing sepsis rates.

This study suggests that surgical technique is of prime importance in the avoidance of wound sepsis in the surgery of pyloric stenosis. Although we appreciate the deficiencies of any retrospective study dealing with wound sepsis, the identification of risk factors has hitherto been deficient; a strategy for the use of prophylactic antibiotic can now be asserted based on the risk factors identified as significant.

Acknowledgements

We would like to thank the surgeons at the Royal Aberdeen Children's Hospital for allowing us to study the case records of their patients, Mr Z. H. Krukowski for his advice on the manuscript, and Professor Kerridge for help and comment on statistical method.

Twenty-five patients with proven gastric outlet obstruction secondary to peptic ulcer disease were treated by endoscopic balloon dilatation using 'through the scope' balloons. The stricture could not be negotiated in one patient. Two patients continued to have gastric outlet obstruction despite the dilatation and required surgery. Two patients have returned up to 11 weeks after treatment with signs of recurrent gastric outlet obstruction. Twenty patients (80 per cent) remained asymptomatic (follow-up: median 9 months, range 2–24 months).

Keywords: Gastric outlet obstruction, pyloric stenosis, dilatation

Benign peptic pyloric stenosis has traditionally been treated by surgery[1]. Recently hydrostatic and pneumatic balloons for gastrointestinal strictures have been developed[2,3] and have been shown to be effective in the management of oesophageal strictures. Initial results with pyloric stenosis using wire guided balloon dilators under fluoroscopic control have been encouraging[4] although up to 26 per cent of patients have been found to be unsuitable[5]. Another report quoted encouraging early results in gastric outlet obstruction using the 'through the scope' balloon but information on patient selection was lacking[5]. We describe our 2-year results using balloon dilatation under direct vision.

Patients and methods

Between November 1986 and November 1988, 25 patients (20 men and five women) with benign pyloric stenosis were investigated in the surgical gastroenterology unit. The median age of the patients was 68 years (range 19–86 years). Sixteen (64 per cent) were over 60 years of age and nine had serious associated illnesses. All patients had presented to our surgical unit as emergencies with persistent effortless vomiting. There was, in all patients, a succussion splash indicating gastric outlet obstruction All of the patients had lost weight before admission (*Table 1*) and had a history of dyspepsia. Five patients had hypochloraemic alkalosis and a further ten were clinically and biochemically dehydrated. Gastric dilatation, outlet obstruction and barium retention were confirmed in ten patients using contrast radiography. All patients were treated by rehydration, nasogastric suction and intravenous fluids and were investigated by upper gastrointestinal endoscopy, when the passage of a 9-mm endoscope through the obstruction was found to be impossible. No patient had any evidence of malignancy on endoscopic biopsy of the pyloric region

As these patients were considered to be candidates for surgery, endoscopic dilatation was attempted in the first instance. Dilatations were performed under intravenous sedation using Diazemuls® (Kabi Vitrum Ltd., Uxbridge, UK; median dosage 5 mg, range 2·5–10 mg) and pethidine (median dosage 12·5 mg, range 0–25 mg). A 180 cm polyurethane catheter (TTS® 12 and 15 mm, Microvasive, Milford, Massachusetts, USA) was passed into the lumen of the pylorus and positioned across the stricture. The balloon was then inflated with a 10 ml syringe containing contrast medium and the entire procedure was followed under X-ray control. After the balloon was completely distended it was kept in place for 3 min The procedure was repeated until the stricture was dilated to 15 mm

Results

All patients tolerated the procedure well, experiencing no more apparent discomfort than with a routine endoscopy. Only one stricture proved to be unnegotiable with the balloon. This patient was treated by surgery. In the remaining 24 patients, dilatation was completed such that a 12·8 mm endoscope (Olympus G1F 1T®, Olympus Optical Company, Tokyo, Japan) could be passed into the duodenum with ease. Three of the patients had strictures that were difficult to negotiate with the 'through the scope' balloon and the use of a guide-wire assisted balloon dilatation was required. Of the successfully dilated patients 14 had evidence of active duodenal ulceration. Symptoms of gastric outlet obstruction persisted in two patients for 7 days after treatment. On clinical examination and repeat endoscopy evidence of recurrent gastric outlet obstruction was found and they were treated surgically. Twenty-two patients were discharged home on maintenance doses of H_2 blockers and on a normal diet.

Patients were followed up at 4 weeks and then at intervals of 2 months. All patients underwent repeat endoscopy at 4 weeks but thereafter were only investigated if symptoms or signs of gastric outlet obstruction were present.

Two patients re-presented with symptoms of outlet obstruction at 8 and 12 weeks after dilatation and required surgical intervention. The remaining 20 patients are well and are without endoscopic or clinical evidence of gastric outlet obstruction (follow-up: median 9 months, range 2–24 months). No complications related to the dilatation procedure were encountered in any of the patients studied.

Discussion

Pyloric obstruction has been considered to be an absolute indication for surgery. Classically, the stenosed area is either resected (Polya gastrectomy), reopened (pyloroplasty) or bypassed (gastroenterostomy). Intraoperative dilatation of the pylorus using Hegar dilators at the time of highly selective vagotomy was first described by Johnston *et al.* in 1973[6] with good results. It was therefore suggested that the fibrous stenosis once dilated could be prevented from restenosing if acid output were reduced. Taylor has recently described a pyloric dilating balloon that fits over the endoscope[7], but the prerequisite for this treatment is that the stricture should be wide enough to admit the endoscope. Hogan *et al.*[4] used balloon dilatation under fluoroscopic control and demonstrated improvement in symptoms in 12 patients. Some difficulty in pushing the balloon through the pylorus has been experienced using this technique. Balloons that could pass through the biopsy channel of a therapeutic endoscope ('through the scope' balloons) have recently been developed. In patients with severe deformity of the bulb, passage of the balloon through the stenosis may be difficult or impossible. The more recent

development of a 'through the scope' balloon that has a central lumen allowing the passage of a guide wire has made negotiation of these strictures easier.

The 'through the scope' balloons are manufactured for single use only. However, they may be resterilized by Cidex® (Surgikos, Livingston, UK) immersal for reuse. One of the safety features of this form of balloon is its inherent low compliance. This ensures that the shape of the balloon is maintained despite the inflation pressure produced. These balloons are not durable and are prone to rupture if over inflated. The use of a pressure gauge may be employed to reduce the incidence of such disruption.

The period of dilatation in our series lasted for 3 min and was chosen arbitrarily at the start of the study. Under X-ray screening the contrast filled balloon was monitored carefully. Early experience showed that 'waisting' of the balloon by the stenosed pyloric channel occurred commonly. This 'waisting' resolved within 2 min of the dilatation. We feel that once this 'waisting' has disappeared the radial effect of the dilatation is achieved and prolongation of the procedure time is not necessary.

Our results show that the majority of patients with severe pyloric stenosis can be treated successfully by balloon dilatation with excellent immediate and medium term results. Although bleeding and perforation are potential complications of this technique, they were not encountered in this series. The incidence of restenosis cannot yet be defined but this technique may provide a useful alternative to surgical intervention in poor risk patients.

Effects of a somatostatin analogue (SMS 201-995) on the growth and development of hepatic tumour derived by intraportal injection of Walker cells in the rat

Administration of a long acting analogue of somatostatin, SMS 201-995 (2 μg subcutaneously twice a day) for 3 weeks after intraportal administration of Walker cells significantly inhibited their growth and development in the liver. This was not due to a direct cytotoxic effect of the analogue on Walker cells whose growth was stimulated in vitro. *Furthermore, SMS 201-995 had no effect on the growth of Walker cells implanted into the thigh of rats suggesting that the inhibitory action of the analogue could be confined to tumour cells growing in the liver. Further studies suggested that the inhibitory effect of SMS 201-995 on the growth of Walker cells in the liver could be related to a marked stimulation of the hepatic reticuloendothelial system, by a reduction in portal venous flow in the early stages of treatment or by a combination of these effects. Further studies are required to delineate more precisely the mechanism whereby SMS 201-995 inhibits the growth of hepatic tumour derived from intraportal administration of Walker cells.*

The activity of the fixed component of the hepatic reticuloendothelial system (RES), the Kupffer cells, influences the growth and development of liver metastases. Thus inhibition of hepatic RES activity by gadolinium chloride significantly increases the growth of hepatic metastases in experimental animals[1]. Furthermore, Kupffer cells have been shown actively to phagocytose cancer cells *in vivo*[2]. Consequently stimulation of hepatic RES activity may be of benefit in the treatment of liver metastases.

Growth of hepatic micrometastases is dependent on their blood supply which in the first instance is derived from the portal vein[3]. Therefore splanchnic vasoconstriction which reduces portal venous inflow may also inhibit the early growth and development of liver metastases.

SMS 201-995, a long acting analogue of somatostatin, is a potent stimulator of the hepatic reticuloendothelial system[4] and reduces portal venous flow in rats[5]. Possibly by stimulating hepatic RES activity and reducing portal venous flow, SMS 201-995 may influence the growth and development of a liver tumour. Therefore the purpose of this study was to investigate the effects of SMS 201-995 on the growth and development of experimentally derived hepatic tumour in the rat.

Materials and methods

Percentage hepatic replacement

Forty male Fisher rats (Charles Fisher, UK) weighing between 240 and 310 g were anaesthetized by an intraperitoneal injection of sodium pentobarbitone (6 mg/100 g). Through a midline incision, the portal vein was exposed and 4×10^6 Walker carcinosarcoma cells injected intraportally. The needle was allowed to remain in the portal vein for about 30 s after completion of the injection to avoid spillage of the tumour cells into the peritoneal cavity. Twenty rats received 2 μg SMS 201-995 in a volume of 0 1 ml subcutaneously twice a day for 3 weeks, beginning on the day they were injected with Walker cells. A control group was dosed similarly with the same volume of normal saline. Three weeks later the rats were killed, and the livers were removed, examined macroscopically for the presence of overt tumour and then fixed in formal saline. The percentage hepatic replacement of the liver by tumour was assessed microscopically using the point sampling technique. In brief, this technique involves projecting the microscope slide onto a graph paper screen and counting the number of micrometastases at the intersects.

Hepatic uptake of ^{99m}Tc-sulphur colloid (^{99m}Tc-SC)

Forty-eight rats received 4×10^6 Walker cells intraportally as described above A treatment group ($n=24$) received 2 μg SMS 201-995 twice a day. A control group was similarly dosed with isotonic saline. The control and treated groups were divided into subgroups comprising six rats each and hepatic and splenic RES activity assessed at 24 h and 1, 2 and 3 weeks after intraportal injection of Walker cells All rats were anaesthetized with intraperitoneal sodium pentobarbitone and the femoral vein was cannulated with a 2Fr cannula. Each rat received 2·5 MBq ^{99m}Tc-SC intravenously, and 20 min later the animals were bled, killed and the liver and spleen excised and weighed. The radioactivity in the liver, spleen and blood was counted in a Philips well γ-counter (Pye Unicam Ltd., Cambridge, UK) The activity of the hepatic and splenic RES was expressed in terms of the ratio of liver:blood and spleen:blood ^{99m}Tc-SC.

$$\text{Liver:blood} = \frac{\text{c.p.m./g liver}}{\text{c.p.m./ml blood}}$$

$$\text{Spleen:blood} = \frac{\text{c.p.m./g spleen}}{\text{c.p.m./ml blood}}$$

Hepatic haemodynamics

Forty-eight rats received an intraportal injection of 4×10^6 Walker cells as described previously Twenty-four rats were given 2 μg SMS 201-995 subcutaneously twice a day beginning on the day they were injected with tumour cells. A control group of 24 rats was dosed similarly with the same volume of isotonic saline. Hepatic haemodynamics were investigated at 24 h, 1, 2 and 3 weeks after administration of Walker cells The right femoral artery was cannulated with a 2Fr cannula connected to a pressure transducer for measurement of blood pressure. Through a midline incision the portal vein was mobilized An electromagnetic flow probe connected to a blood flowmeter (Gould, Statham, Model SP2202, Gould Medical Ltd., Lutterworth, UK) was placed around the portal vein cranial to the junction with the pancreaticoduodenal vein. The probe was adjusted to zero after placement on the portal vein by completely occluding the flow.

Splanchnic vascular resistance was calculated using the following formula.

$$\underset{(\text{mmHg min ml}^{-1})}{\text{Splanchnic vascular resistance}} = \frac{\text{Mean arterial blood pressure (mmHg)}}{\text{Portal venous flow (ml min}^{-1})}$$

0007–1323/89/1149–03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

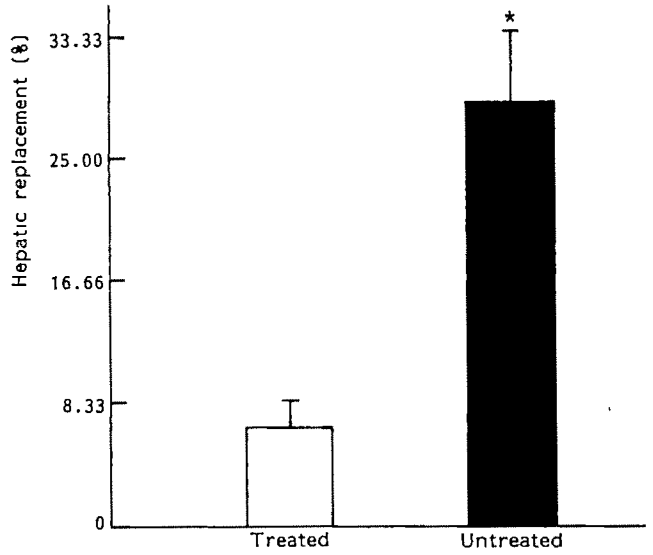

Figure 1 *Percentage hepatic replacement of liver tissue by tumour in control rats (■) and those treated with SMS 201-995 (□) 3 weeks after intraportal administration of Walker cells. The vertical bars represent the s.e.m.*, * P<*0·001 SMS treated* versus *control*

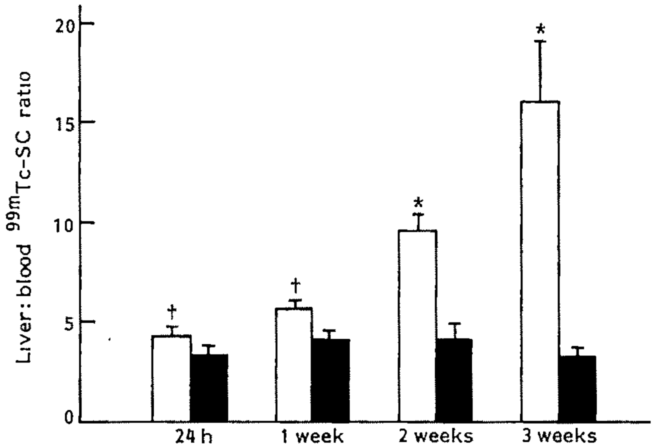

Figure 2 *Alterations in hepatic reticuloendothelial system activity expressed as ratio of liver blood and spleen blood ^{99m}TC-sulphur colloid in rats treated with SMS 201-995 (□) or saline (■) at various times after intraportal administration of Walker cells The vertical bars represent s.e m.*, P⩽*0·01*, † P⩽*0·05 control* versus *SMS 201-995 treated animals*

The effects of SMS 201-995 on the growth and development of Walker cells implanted into the thigh of rats

Twenty rats received an inoculation of 10^8 Walker cells subcutaneously into the right thigh. A treated group ($n = 10$) received 2 μg SMS 201-995 in 0·1 ml subcutaneously twice a day for 2 weeks. A control group was dosed similarly with the same volume of isotonic saline. The animals were then killed and the tumour excised and weighed

The effects of SMS 201-995 on the growth of Walker cells in vitro

Cultures of 10^5 Walker cells were incubated in Williams medium supplemented with fetal calf serum at 37°C in a humidified atmosphere in the presence of 1 μg SMS 201-995 ($n = 10$) or saline ($n = 10$) for 4 days and the cells counted.

Statistical analysis

The statistical significance of any differences between control and treated animals was evaluated using a Student's *t* test for unpaired data

Results

Percentage hepatic replacement

The mean(s.d.) weight of the livers from control animals 15·76(4·31) g was significantly greater than from rats treated with SMS 201-995 (12·04(3·22) g, $P < 0·005$). All control animals had widespread overt liver metastases 3 weeks after administration of the Walker cells. In contrast in the 20 rats treated with SMS 201-995, eight had no obvious tumour and 12 only solitary tumours, the majority of which occurred in the right lobe. The percentage hepatic replacement measured microscopically in the SMS treated rats was significantly less than in the control animals (*Figure 1*)

Hepatic and splenic uptake of ^{99m}Tc-SC

The liver to blood ratios and spleen to blood ratios of ^{99m}Tc-SC activity were significantly greater ($P < 0·01$) in the SMS 201-995 treated animals then in the controls throughout the experiment (*Figures 2* and *3*).

Hepatic haemodynamics

Portal flow was significantly lower ($P < 0·05$) in the SMS treated rats than in the controls 24 h after the start of treatment. Thereafter, no significant difference between control and treated animals was observed (*Figure 4*). Splanchnic vascular resistance was significantly increased in the SMS 201-995 treated animals compared with the controls only during the first 24 h (*Table 1*).

The effect of SMS 201-995 on the growth and development of Walker cells implanted into the thigh of rats

SMS had no significant effect on the growth of Walker cells implanted into the thigh. The mean(s.d.) tumour weights in the control rats were 17·07(9·2) g compared with 20·99(9·5) g in the SMS treated animals ($P > 0·05$).

The effect of SMS 201-995 on the growth of Walker cells in vitro

Addition of SMS 201-995 to the culture medium containing the Walker cells significantly increased their growth (*Figure 5*).

Discussion

The results of this study clearly show that SMS 201-995 significantly reduces the growth and development of hepatic tumour derived from intraportal administration of Walker cells. This is not due to a direct cytotoxic effect of the analogue on Walker cells whose growth is actually stimulated by SMS

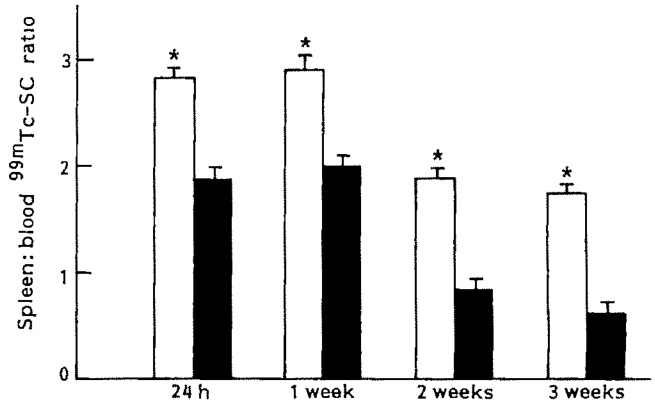

Figure 3 *Alterations in splenic reticuloendothelial system activity expressed as ratio of liver blood and spleen blood ^{99m}TC-sulphur colloid in control rats (■) and animals treated with SMS 201-995 (□) at various times after intraportal injection of Walker cells The vertical bars represent the s.e.m*, * P⩽*0·01 SMS 201-995 treated* versus *control*

201-995 *in vitro*. Possibly the inhibition of the growth and development of Walker cells by SMS 201-995 is related to their location within the liver. This suggestion is supported by the observations in this study that SMS 201-995 had no effect on the growth of Walker cells implanted into the thigh of rats. Furthermore it has recently been shown that SMS 201-995 had no significant effect on the development of colonic neoplasia in carcinogen treated rats[6] but produced a regression of neuroendocrine tumours that had metastasized to the liver[7]. Inhibition of the growth and development of hepatic tumour by SMS 201-995 may be due to three possible mechanisms: stimulation of RES activity, reduction in portal venous inflow and inhibition of hepatotrophic factors such as insulin or glucagon.

The RES is an important component of the immunological defence system of the body against malignancy. The fixed component of the RES in the liver, the Kupffer cells, have been shown to phagocytose tumour cells both *in vitro* and *in vivo*[2]. In contrast, inhibition of the hepatic RES by gadolinium chloride enhances the growth of hepatic tumour cells[1]. In the present study, intraportal administration of Walker cells did produce some stimulation of the hepatic RES activity above normal levels but this was probably insufficient to prevent the growth and development of the large number of tumour cells administered. In contrast the hepatic RES of rats treated with SMS 201-995 was markedly elevated throughout the study and this appears to have been sufficient to inhibit the growth of hepatic tumours either completely or partly. This observation is therefore in accord with previous studies which indicated that SMS 201-995 is a potent stimulator of the fixed and circulating components of the RES in experimental animals and in man[8]. Although the activity of the circulating component of the RES was not measured in this study, SMS 201-995 markedly stimulated splenic RES activity throughout the study The precise role of increased splenic RES activity in relation to impairment of the growth and development of hepatic tumour is unknown. However, it may represent a generalized increase in RES activity, including the circulating components, and this overall stimulatory effect on the RES may contribute to the impaired growth and development of hepatic tumour

In the present study, portal venous flow was reduced and splanchnic vascular resistance was increased initially in rats treated with SMS 201-995 compared with control animals.

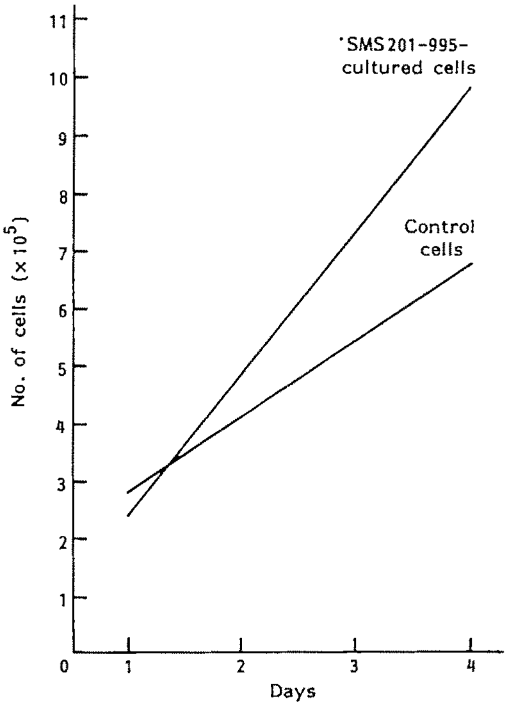

Figure 5 *The effects of SMS 201-995 on the growth of Walker cells incubated* in vitro; *SMS 201-995 treated* versus *control cells*, $P < 0.01$

These observations are consistent with previous reports on the effects of the somatostatin analogue in the cirrhotic rat[5] During their early growth and development, hepatic metastases are dependent on a supply of nutrients from the portal vein[3]. Therefore it is possible that a reduction in portal venous flow elicited by SMS 201-995 in the early stages of development could inhibit the growth of hepatic tumour. After 1 week there was no significant difference in portal venous flow or splanchnic vascular resistance between SMS 201-995 treated and control rats. However, at this stage the hepatic haemodynamics are complicated in the untreated group by the growth of the tumour which could reduce portal venous flow by a mechanical effect Further detailed studies are in progress to evaluate the sequential haemodynamic changes in rats with actively growing tumour and those treated with SMS 201-995.

The prognostic value of nucleolar organizer regions and ploidy status in patients with Dukes' C colorectal cancer was determined. In addition, nucleolar organizer regions and ploidy status were compared with the established prognostic indices age, sex, tumour location and degree of histological differentiation. Fifty-one patients (27 men, 24 women) aged 35–81 years (median 64·8 years) were studied. Five years after presentation, 16 patients were alive and well. Survivors had significantly lower nucleolar organizer region counts (median value and range) in primary tumours 12 (8–15) and lymph node metastases 11 (8–15) than non-survivors 17 (14–25) and 18 (13–25) respectively ($P<0{\cdot}05$)*. Fewer survivors had aneuploid tumours than non-survivors: four survivors compared with 17 non-survivors. In a regression analysis model, nucleolar organizer regions were the most important individual variable for predicting survival* ($\chi^2=15$, $P<0{\cdot}01$) *while ploidy values* ($\chi^2=6$, $P<0{\cdot}2$) *were equivalent to histological differentiation.*

Keywords: Colorectal cancer, DNA, ploidy, flow cytometry, nucleolar organizer region, nucleolus

Dukes' classification was introduced in 1932 to help predict prognosis in rectal cancer[1]. Although modifications of Dukes' original classification[2–4] and degree of histological differentiation as defined by Broders[5] remain the gold standards for prognosis in colorectal cancer, major anomalies are observed. Indeed the unreliability of these prognostic factors is best illustrated by the fact that although one-third of patients with lymph node metastases at presentation become long-term survivors, approximately one-third of patients with Dukes' B tumours die from their cancer irrespective of histological differentiation[6,7]. Consequently, there is a need for more accurate prognostic indices.

The prognostic value of nucleolar organizer regions and tumour cell DNA content is currently being investigated in a variety of human tumours. Nucleolar organizer regions are loops of ribosomal DNA which occur in nuclei and direct ribosome and protein formation[8]. They are accurately identified by the argyrophilia of their associated proteins. It has been suggested that the numbers of nucleolar organizer regions in nuclei may reflect the state of cellular activity or the malignant potential of that cell[9]. Supporting evidence comes from the fact that different numbers of nucleolar organizer regions have been recorded in benign and malignant melanocytic tumours and in low and high grade lymphomas[8,10]. In addition, nucleolar organizer region counts have been shown to be significantly increased in patients with prostatic tumours who are destined to develop metastases[11].

The measurement of cellular DNA content by flow cytometry is reported to be of prognostic value in a variety of human tumours[12–15]. Changes in cellular DNA content reflect changes in chromosome content and ploidy status[12–15]. Thus tumours can be divided into two groups. those with a normal or near-normal diploid DNA content and those with an abnormal DNA content.

The purpose of this study was to determine the prognostic value of nucleolar organizer regions and ploidy status and to compare them with established prognostic indices in patients with surgically resected advanced colorectal cancer.

Presented to the Surgical Research Society in Canterbury on 6 January 1989

Patients and methods

Patients

Sixty consecutive patients who presented between 1979 and 1982 with advanced colorectal cancer were investigated. Nine patients were eliminated from the study There was inadequate archival tissue for examination in five cases and although the other four patients were alive and well at 1 year they were subsequently lost to follow-up. The remaining 51 patients (27 men and 24 women) aged 35–81 years (median 64·8 years) were studied. All patients had their tumours resected and tumour locations and operative procedures performed are listed in *Table 1*. Histological differentiation and Dukes' classification were determined on routinely processed specimens All patients had Dukes' C tumours and eight patients had clinically apparent liver metastases at presentation. Tumours were classified as well differentiated if greater than half the tumour was gland forming, moderately differentiated if gland formation was noted in 20–50 per cent, and poorly differentiated if more than 80 per cent exhibited a solid growth pattern and/or contained cells with extreme nuclear pleomorphism or a marked increase in nuclear cytoplasmic ratio. Sixteen tumours (31 per cent) were considered well differentiated, 24 were moderately differentiated (47 per cent), nine were poorly differentiated (18 per cent) and two (4 per cent) were predominately mucinous. The fate of all patients is known at 5 years

Nucleolar organizer regions

Sections from primary tumours and lymph node metastases were stained for nucleolar organizer regions in all 51 patients. Tissue sections which had previously been fixed in 10 per cent formalin and embedded in

paraffin wax were cut into 4-μm thick sections. These sections were then rehydrated using xylene and graded ethanol solutions. Staining was performed at room temperature for 60 min, using a reaction mixture that comprised 2 per cent gelatin in 1 per cent aqueous formic acid which had been mixed in a proportion of 1:2 volumes with 50 per cent aqueous silver nitrate under darkroom conditions. A 1 per cent methyl green counterstain was applied to each section which was then dehydrated to xylene and mounted.

After staining, representative areas in each section were selected by a pathologist and nucleolar organizer regions were counted by a single observer who was unaware of tumour classification or patient fate. A total of 50 nuclei in each selected area were counted under oil immersion microscopy at a magnification of × 1000 and a median nucleolar organizer region score and a range were calculated. This technique was validated by examining interobserver and intraobserver variations in nucleolar organizer region counts. There were small variations. Two patterns of staining were noted, as previously described[12] Nucleolar organizer regions were visualized as black dots arranged individually (type 1 pattern, simple) or in clusters (type 2 pattern, compound). In type 1 stains, individual nucleolar organizer regions were awarded a score of 1. In type 2 stains, clusters of nucleolar organizer regions were allocated a numerical score according to size by using a graticule in the objective lens. Clusters measuring up to $4 \times 4\,\mu$m were awarded a score of 3, from $4 \times 4\,\mu$m to $6 \times 6\,\mu$m a score of 5 and from $6 \times 6\,\mu$m to $8 \times 6\,\mu$m a score of 7. By this counting technique a single numerical value was obtained for each cell by combining simple and compound nucleolar organizer region scores.

Flow cytometry

A modification of the method developed by Hedley *et al.* to isolate nuclei from formalin-fixed paraffin-embedded tissue was used[16]. Thick sections (50–60 μm) were cut and dried on to glass slides at 50°C for 30 min. Sections were dewaxed in warm xylene for 30 min, placed in cold xylene for 5 min and rehydrated through graded alcohols to distilled water. The tissue was disaggregated with 0·5 per cent pepsin in 0·9 per cent saline with a pH 1·5 for 30 min at 37°C. The digest was centrifuged at 200g for 10 min, washed and then resuspended in 2 ml propidium iodide. After centrifugation and washing, the digest was resuspended in 1 ml of phosphate-buffered saline, syringed three or four times to disaggregate nuclear clumps, and then filtered through a 40-μm nylon mesh. It was not usually necessary to adjust the concentration of nuclei but high concentrations were diluted with phosphate-buffered saline to give approximately 10 nuclei per millilitre. DNA analysis was performed using an FACS 420 flow cytometer (Becton Dickinson, Sunnyvale, California, USA). Red fluorescence (DNA content) was measured between 620 and 740 nm only. The DNA data generated were recorded and stored on floppy disc by an Acorn Archimedes® (Acorn Computers Ltd, UK) computer for subsequent analysis. If possible the fluorescence from 100 000 nuclei was recorded, a minimum of 10 000 nuclei being required to produce interpretable histograms.

The analysis of tissue sections containing normal cells enabled tumour cells with more or less than 2c DNA to be detected. Only histograms with a coefficient of variation of less than eight were accepted. Histograms were classified as aneuploid or diploid and those with a large tetraploid peak were included with the aneuploid group. The detection of tetraploid tumours, especially if they only represent a small fraction of the whole section, is difficult as those tumour cells in G1 have the same DNA content as normal cells in G2 and M. In these cases, a 4c peak representing more than 20 per cent of the whole cell population was designated aneuploid as it is unlikely that normal cells would have such a high G2/M peak. A histogram peak with a shoulder may represent two populations of cells with a small ploidy difference that cannot be resolved from each other but may equally represent technical errors in nuclear preparation or instrument alignment. In these cases analysis was usually repeated and if the shoulder persisted it was considered aneuploid.

Statistics

Correlations between nucleolar organizer region counts and clinical and pathological features (age, sex, tumour location, histological differentiation, and survival time) were examined using the Mann–Whitney U test. Correlations between ploidy values and these features were examined using the χ^2 test The independent significance of individual prognostic variables was determined using Cox's multivariate regression analysis

Results

Five years after presentation 16 patients were alive and well. Of the 35 patients who succumbed, one died as a result of a myocardial infarction and one as a result of a pulmonary embolus. All other deaths were cancer related. The median survival time for non-survivors was approximately 11 months

Nucleolar organizer regions

Nucleolar organizer region counts in survivors and non-survivors are shown as median values and ranges in *Table 2*. Similar counts were detected in both primary tumours and lymph node metastases (*Table 2*). Survivors had significantly lower nucleolar organizer region counts than non-survivors (*Table 2*). Patients with liver metastases had higher counts (20, range 16–22) than patients without liver metastases (16, range 12–21) but the difference was not significant. Higher counts were associated with decreasing histological differentiation with values of 15 (range 12–21) for well-differentiated tumours compared with 17 (range 10–22) for moderately differentiated tumours and 19 (range 16–25) for poorly differentiated tumours but this difference was not significant. There was no correlation between nucleolar organizer region counts and tumour site, age or sex.

Ploidy values

Satisfactory DNA histograms were obtained for primary tumours examined by flow cytometry in 40 patients. Although survivors and patients without liver metastases had a lower percentage of aneuploid tumours the difference was not significant (*Table 3*). Ploidy values did not correlate with degree of histological differentiation with nine out of 14 (64 per cent) well-differentiated tumours, nine out of 20 (45 per cent) moderately differentiated tumours and three out of five (60 per cent) poorly differentiated tumours being aneuploid. There was no correlation between ploidy values and age or sex.

Factors affecting survival

In a regression analysis model nucleolar organizer regions were the most important individual variable for predicting survival ($\chi^2=15$, $P<0·01$) while ploidy values ($\chi^2=6$, $P=0·2$) were as accurate as histological differentiation ($\chi^2=7$, $P=0·2$). Tumour site, age and sex were not of prognostic value.

Discussion

Conventional clinical and pathological indices are unable to predict accurately tumour recurrence or survival time in colorectal cancer. Numerous prognostic factors such as Dukes' classification, modifications of Dukes' classification which take into account depth of penetration and location and number of involved lymph nodes, Broders' histological differentiation, patients' age and sex, tumour location, tumour fixation and carcinoembryonic antigen levels are currently used. It is

Table 3 *Distribution of aneuploid and diploid tumours in survivors and non-survivors and patients with and without liver metastases*

	Aneuploid (n)	Diploid (n)
Survivors	4	6
Non-survivors	17	13
Patients with liver metastases	6	2
Patients without liver metastases	15	17

estimated that at best they accurately predict recurrence in non-metastatic invasive colon cancer in only 50–75 per cent of cases[17]

Prediction of survival is no more precise and 5-year survival rates ranging from 19 to 62·3 per cent according to age, sex and tumour site have been reported[18]. Patients undergoing 'curative resections' defined as removal of all macroscopic tumour have been shown to have a significant survival advantage[19]. Yet it has been demonstrated that a considerable proportion of patients thought to have a Dukes' A, B or C lesion at the time of surgery and believed by the surgeon to have undergone a curative resection have occult hepatic metastases from which they subsequently die[20].

Most of the prognostic indices that are currently used are obtained at the time of tumour resection and subsequently from examination of the resected specimen. Thus they are not available before surgical intervention. Williams *et al.* have shown that preoperative staging of rectal neoplasms could influence subsequent management[21] Using present advances in technology, biochemistry and histopathological techniques they achieved a more accurate staging than hitherto. They concluded that this improved accuracy would alter preoperative and intraoperative decisions, preventing some patients receiving adjuvant therapy as well as selecting patients more accurately for the correct treatment. Consequently prognosis might be improved.

Clearly a number of problems exist. Dukes' classification, modifications of Dukes' classification and the Astler–Coller system of staging are all used, resulting in much confusion[2–4]. Although the TNM system was introduced in order to standardize the pathological staging and make it more comprehensive it has not proved popular[22] This system does give more information about the extent of direct tumour spread and lymph node involvement, as well as taking into account the presence of distant metastases. Other inadequacies of existing staging classifications relate to their failure to take into account local invasion of contiguous tissues and structures, a characteristic which in some studies has been shown to be of greater prognostic significance than involvement of lymph nodes[23,24].

Another difficulty is that morphological features such as depth of invasion and grade rely on the subjective evaluation of the pathologist. Findings may vary enormously as shown by one study dealing with interobserver and intraobserver reproducibility of results[25]. Furthermore, colon cancers have been shown to contain heterogeneous cell populations suggesting that tumours evolve over time with waxing and waning of their cell subpopulations; current prognostic indicators obtained at only one point in time may thus be insufficient for the ongoing management of cancer patients[7].

Initially it was anticipated that assessment of ploidy status by flow cytometry might overcome some or all of these problems. It was reported that 65 per cent of patients with DNA diploid tumours survived 5 years compared with only 7·5 per cent of those with DNA aneuploid tumours[26]. Subsequent investigators have disagreed on the prognostic value of ploidy status. In patients undergoing a 'curative' resection, one study showed that DNA ploidy status was the single most important prognostic factor[27].

Different investigators reported DNA ploidy status to be of individual and independent significance in a multivariate analysis but weaker than Dukes' classification[28,29] Other authors have failed to support these findings, showing instead that although DNA ploidy was of individual prognostic significance it was not of value when included in a regression analysis model[30]. Two other studies found no significant differences in survival between patients with DNA diploid tumours and those with DNA aneuploid tumours[31,32]. In a prospective study of prognostic factors it was found that the surgeons' assessment of operability was the strongest predictor of survival followed by the pathological classification and the patient's age and that DNA ploidy status conferred no independent survival value[6]. In the present study ploidy status was a poor prognostic indicator.

The prognostic value of nucleolar organizer regions has not been previously determined in colorectal cancer. In this study nucleolar organizer regions provided prognostic information over and above that obtained from assessment of haematoxylin and eosin stained sections. Nucleolar organizer regions were the single most reliable prognostic variable for predicting survival. In addition they correlated with decreasing degrees of histological differentiation and with the presence of liver metastases. As for all techniques that could have an application in diagnostic pathology it is important that the method is reproducible in different laboratories and that the reaction can be interpreted with ease. Although evaluation of nucleolar organizer regions is subjective in nature the counting technique used in this study was validated. Interobserver and intraobserver variations in nucleolar organizer region counts were sought and only minor differences were found. Although staining is technically easy to perform and relatively inexpensive, counting nucleolar organizer regions is at present laborious and time consuming.

In conclusion it is unlikely that a single accurate prognostic indicator which can be applied to all cases will emerge in colorectal cancer. In this study the ability of ploidy status to predict survival was disappointing. Considering the varied and contradictory findings of the many investigators who have examined its prognostic value, its potential for future development as a prognostic indicator in colorectal cancer would appear to be limited. In contrast, nucleolar organizer regions would appear to have considerable potential The introduction of a computer program to count nucleolar organizer regions would allow objective evaluation and would allow counting techniques to be standardized thus eliminating variations in nucleolar organizer region scores reported from different laboratories and allowing meaningful comparison of different studies.

Differential diagnosis of subungual melanoma from a surgical point of view

V. K. Shukla and L. E. Hughes

University Department of Surgery, University of Wales College of Medicine, Heath Park, Cardiff CF4 4XN, UK

Correspondence to.
Professor L. E. Hughes

Subungual lesions referred to a surgical unit over a 17-year period have been reviewed to assess problems of differential diagnosis and management of suspected subungual melanoma. Such lesions are uncommon, even in a unit with interest in melanoma. Only four melanomas were seen for primary treatment, and eight in all, during the period. We describe the clinical features of other subungual lesions seen in surgical patients which might help in their differentiation from melanoma. Differential diagnosis and a management policy to achieve early diagnosis are discussed in the light of data from this series and study of the relevant literature.

Keywords: Subungual melanoma, differential diagnosis

Subungual melanoma is one of those striking conditions the rarity of which is obscured by the manner in which it catches the imagination of medical author, teacher and student alike. Yet, because of its rarity, it is likely to be misdiagnosed or mismanaged in spite of this universal awareness. It was first described by Boyer[1] in 1854 as a rare tumour. Hutchinson[2], in 1886, called it a melanotic whitlow because it often resembled an infection. Hutchinson described its clinical features from a personal experience of six cases and recognized that injury often drew attention to the lesion and tended to be blamed for its origin. Even now, 100 years later, subungual melanoma is frequently misdiagnosed[3], probably because of its non-specific clinical features and the rarity of the lesion. A review of 5727 malignant skin lesions at the Skin Cancer Unit of the New York University School of Medicine[4] revealed only eight subungual tumours of which only one was a subungual melanoma. Pack and Oropeza[5] described 72 patients with subungual melanoma representing 2·6 per cent of all the melanomas they saw, but this was within a highly specialized referral practice. Other reports have indicated an incidence of from 1·6 to 3·5 per cent[7–9]. In addition there are sporadic reports of subungual melanoma[5,6,10–19] and the published literature indicates a low index of suspicion on the part of clinicians[20,21]. From these reports, it is difficult to determine frequency of subungual melanoma relative to other subungual conditions presenting to surgical clinics.

In view of the difficulty of clinical diagnosis and the consequent problems of management, we have reviewed our own experience with subungual lesions over the past 17 years together with the relevant literature to determine which diagnostic features of different subungual lesions may be confused with melanoma, and to provide a management policy that will lead to an early definitive diagnosis.

The Cardiff experience

The Cardiff experience of subungual lesions is limited and clearly reflects the bias of surgical referral; experience in a dermatology clinic would, doubtless, be different. All subungual lesions, with the exception of haematoma, proved to be rare. Only eight lesions suspicious of melanoma (other than haematoma) were seen in our clinic in a 17-year period. Only four cases of primary referral of subungual melanoma were seen among 445 patients with melanoma from 1972 to 1988. In addition, a further four cases were seen during the same period as secondary referrals after the primary lesion had been excised.

All patients were Caucasians; there were five men and three women. The digits involved were five toes and three fingers. The age of the patients ranged from 53 to 76 years. The clinical appearance of the tumour varied but most of the patients noted a mass below the nail, usually associated with the loss or destruction of the nail (*Figure 1*). Three patients presented with pigmentation and ulceration of the nail bed. Some lesions began as a subungual pigmentation and after several months became ulcerated or painful. History of trauma was available in three patients. The lesion usually failed to heal, became infected and initial diagnosis of pyogenic granuloma was made but biopsy revealed melanoma. Clinically, four of the eight lesions were incorrectly diagnosed. Frozen sections from three patients confirmed malignant lesions but failed to confirm melanoma, which was finally confirmed on paraffin section. These patients were treated by metacarpophalangeal or metatarsophalangeal or interphalangeal amputation. Six of the eight patients underwent lymphadenectomy (axillary or inguinal). Five had therapeutic lymphadenectomy with from two to five nodes positive, while one patient had prophylactic lymphadenectomy (nodes negative). Six of the eight patients died from the disease within 17–50 months. Two patients are alive and well after 48 and 96 months. During the same period, 11 melanomas of a digit were seen which did not involve the finger or toe-nail.

We have never seen a simple subungual naevus, either after referral or as a chance observation. Of the eight primary subungual melanomas reviewed, only one resembled a haematoma (which it did very closely). The very much commoner situation was for a haematoma to be suspected as being a melanoma. The exact number of haematomas suspected to be melanoma seen during this period has not been recorded, but it is estimated at 20 (i.e. haematomas presenting without history of trauma). No cases of eczema or fungal infection of the nail have been referred for surgical opinion to exclude melanoma, although we frequently see these conditions in normal clinical practice. It would appear that melanoma, although rare, is readily misdiagnosed as a fungal infection, but that true fungal infections are recognized accurately by dermatologists and are diagnosed without referral for biopsy.

Clinical features

Subungual melanoma is commonly seen in patients aged 50–70 years. It is equally distributed in men and women, and has a

relatively greater frequency in black people than in white people[4,22]. The most common digit to be involved is the thumb and great toe[4].

Symptoms and signs

The majority of the patients present because of the altered appearance of the digit, rather than primarily because of a pigmented lesion. A history of pre-existing pigmented lesions is present in about one-quarter of the cases[4,6] and is frequently attributed to a preceding injury. The common presenting symptoms are pain, discomfort, deformity of the nail, ulceration, swelling and bleeding from the nail bed. Unfortunately, all these represent late disease. These symptoms frequently lead to various forms of medical treatment for 2–3 years before the true nature of the condition is recognized. Subungual melanoma at the usual stage of presentation is recognized with relative ease (*Figure 1*). It then appears as a black, fungating, well demarcated ulcer which has elevated the nail and spread on to the nail fold. Thickening, splitting, distortion or complete destruction of the nail plate may occur, leading to variable degrees of pain, inflammation, pigmentation and discharge. Up to 20 per cent of lesions are amelanotic (*Figure 2*), and are often diagnosed as fungal infections or chronic paronychia. The local nature is important – neither the whole nail nor the whole nail fold is affected. Improvement in outlook is likely only when the condition is diagnosed at a stage when it still resembles a haematoma (*Figure 3*).

Helpful diagnostic features in earlier lesions are bands or streaks of pigmentation in the nail bed, a coal-black border at the edge of the lesion and involvement with pigmentation of the adjacent eponychium. This eponychial pigmentation carries similar diagnostic significance to the narrow rim of superficial spreading change adjacent to a nodular melanoma. Melanoma is likely to have detectable thickness, so that the nail is locally raised. This may or may not occur with haematoma. The 20 per cent of lesions which are amelanotic are particularly likely to be confused with chronic paronychia on clinical grounds.

Although bilateral subungual melanoma has been recorded[3] it normally involves a single digit. The diagnosis must be considered and excluded in any of the following situations: (1) pigmentation of the nail bed; (2) persistent onychia, paronychia or chronic granulation tissue of the nail bed; (3) unexplained splitting, cracking or displacement of the nail bed; and (4) persistence of a lesion following trauma of the nail. In any of these situations, prolonged periods of trial therapy must be avoided, and a definitive diagnosis should be made within 6 weeks. The conditions that require consideration in the differential diagnosis are listed in *Table 1*.

Differential diagnosis of subungual melanoma

Subungual haematoma

Subungual haematoma is typically acute, clearly related to trauma, and sufficiently painful to demand release. Less commonly, this condition appears gradually, painlessly and without a history of trauma. The mechanism of this form of haematoma, which causes the major diagnostic problem in relation to melanoma, is unknown.

Haematomas usually have an irregular outline (*Figure 4*) rather than the straight edge of the melanoma, but they may also have sharply demarcated straight edges (*Figure 5*). They do not usually involve the eponychium or nail fold, as is usual in all except the smallest of melanomas. Stone and Mullins[23] have shown that a haemorrhage in the matrix area is incorporated into the nail plate while the more usual haematoma distal to the lunula remains subcuticular, attached to the nail itself. Hence, when the nail is removed in the case of simple haematoma, the haematoma comes off with the nail as a dried, rather dehydrated, layer attached to its under-surface. In typical examples where it is considered justifiable to observe the lesion, most haematomas will grow along the nail with obvious movement shown over a period of 4–6 weeks, and with a depigmented area appearing in the region of the lunula. However, non-migrating haematomas are sometimes seen. If a melanoma grows along the nail plate in a similar fashion to a haematoma, the lesion will remain obvious in the lunula area and will almost certainly involve the eponychium.

Paronychia

Paronychia is the commonest inflammatory lesion of the nail fold, and acute paronychia causes little diagnostic difficulty. However, chronic paronychia may resemble an amelanotic subungual melanoma to a degree that frequently leads to misdiagnosis. The clinical features are tenderness, redness, purulent discharge and a rapid course with absence of pigmentation. In chronic paronychia the nail fold is swollen and uncomfortable, but the nail itself is not noticeably lifted from the nail bed – even when there is a clear space between the nail fold and the nail plate. The nail is often irregular and yellow or greenish in colour.

Subungual melanoma is predominantly subungual, in contrast to chronic paronychia. On the other hand, an amelanotic melanoma of the nail fold (i.e. not subungual) may resemble chronic paronychia, but will usually spread on to the adjacent skin, well away from the nail fold.

Pyogenic granuloma

This condition may occur in the nail sulcus but does not occur as a specifically subungual lesion. Its features in this region are similar to those elsewhere: a mass of pinkish watery granulation tissue sometimes covered by a crust. The history is rapid: just a few weeks and often follows a minor injury. It is readily diagnosed by biopsy.

Onychomycosis nigricans

This fungal infection of the nail produces a black pigmentation which is easily mistaken for subungual melanoma. It is generally present on more than one nail and often on both limbs, whereas melanoma is usually confined to a single digit. The two lesions can occur together[20] and biopsy should be carried out if a single nail appears atypical.

Glomus tumour

The majority of these tumours occur on the hand and account for 1–2 per cent of all hand tumours[24]. They are characterized by intense, often pulsating, pain which leads to an equally characteristic reaction: patients draw their hand away before the clinician can even attempt to examine it, because the anticipated pain is so intense. The lesion is visible through the nail plate as a small bluish to reddish-blue spot (*Figure 6*). The slow growth and its exquisite sensitivity help to differentiate the glomus tumour from subungual melanoma. When removed, a characteristic bluish-pink lesion resembling granulation tissue is seen (*Figure 7*) and it has usually eroded a depression in the underlying bone of the phalanx, from which it is readily

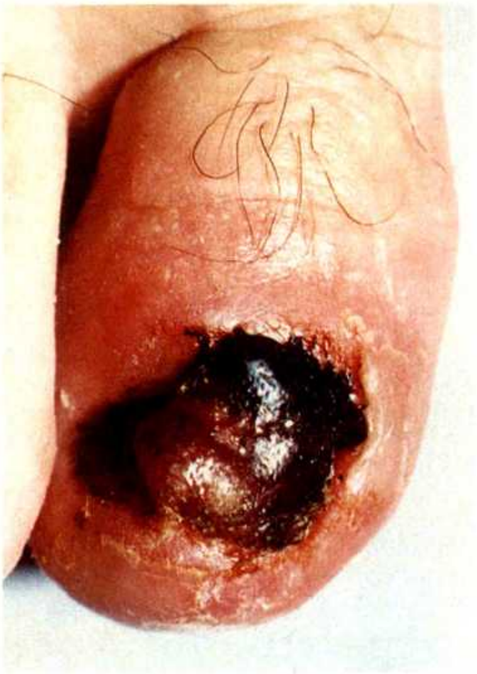

Figure 1 *A typical (late) subungual melanoma, as commonly diagnosed. Note the superficial spreading element extending on the nail fold laterally*

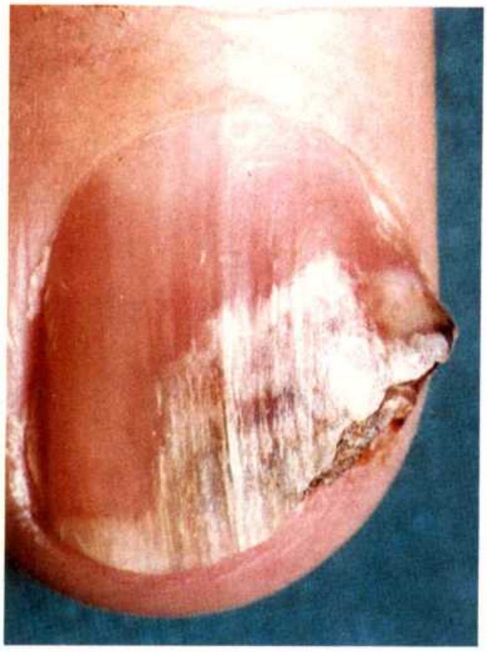

Figure 2 *Amelanotic melanoma. The focality of this lesion suggests a tumour, as most of the nail and nail fold is normal*

curetted. It is not usually necessary to remove the overlying nail matrix.

Benign naevus

Benign naevus is reported as arising in childhood so there is a known long history. It is said to be more common in pigmented races and uncommon in Caucasians. We have not seen a single example, and the only patient referred and thought to have this lesion was followed for 1 year, by which time the lesion had gradually grown out of the nail and therefore appeared to be a reaction to chronic trauma. Many of the lesions illustrated as benign naevi do not seem to have been biopsied. Although said to be common in Negroes and other heavily pigmented races, it is noteworthy that in two surveys of naevi in black races[25,26] no mention is made of subungual naevus. It would seem undoubted that naevoid lesions under the nail in Caucasians are far more likely to be malignant than benign, and it would seem prudent to biopsy any such lesion that might be encountered[27].

Subungual exostosis

This not uncommon condition is most often seen on the great toe. It is particularly frequent in young people and presents as a firm swelling below the nail near the tip. In time it will displace the nail. The triad of pain, nail deformity and radiographic abnormality, together with a clearly defined outline of the lesion, is usually diagnostic. Treatment consists of excision of the excess bone.

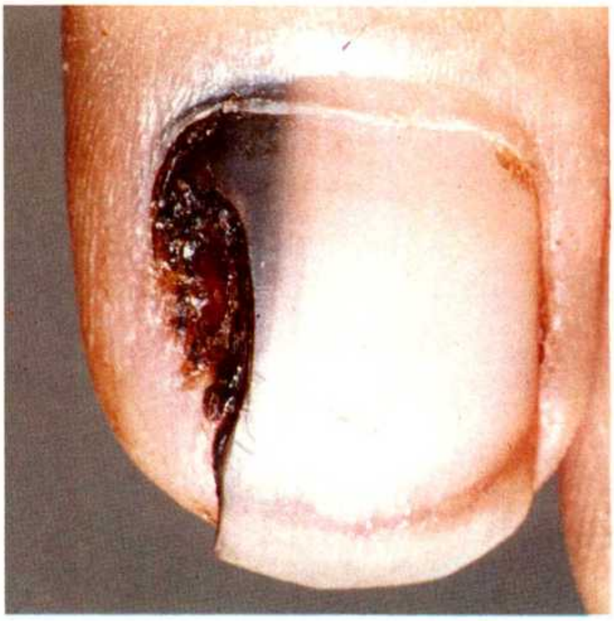

Figure 3 *An earlier (although still fatal) subungual melanoma. Note the straight edge, the involvement of the basal nail fold, and the obvious 'thickness' of the lesion*

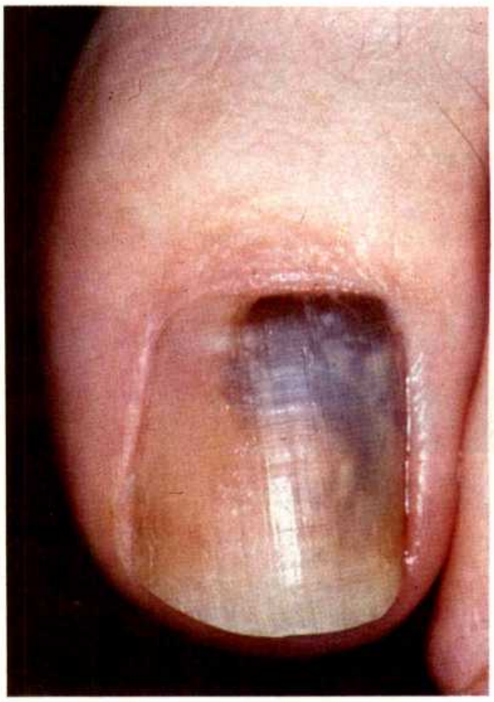

Figure 4 *A painless, subungual haematoma. Note that the nail fold is unaffected*

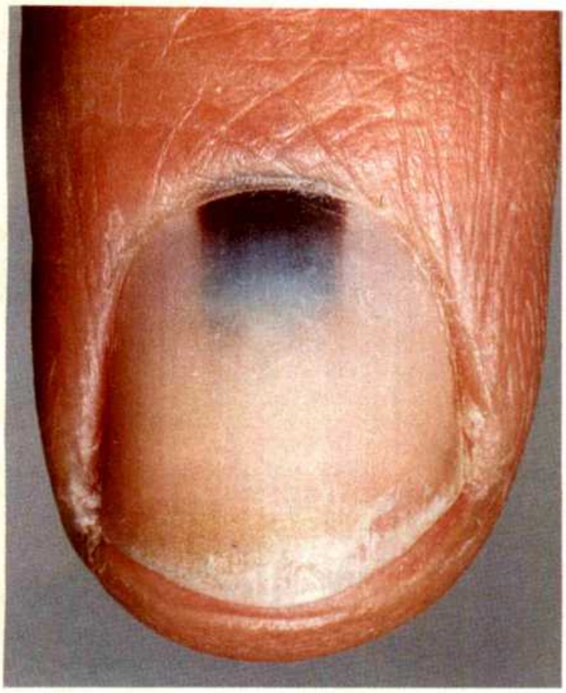

Figure 5 *Painless, spontaneously appearing, subungual haematoma. Note the lack of involvement of the nail fold, which would suggest melanoma* (cf. Figure 3)

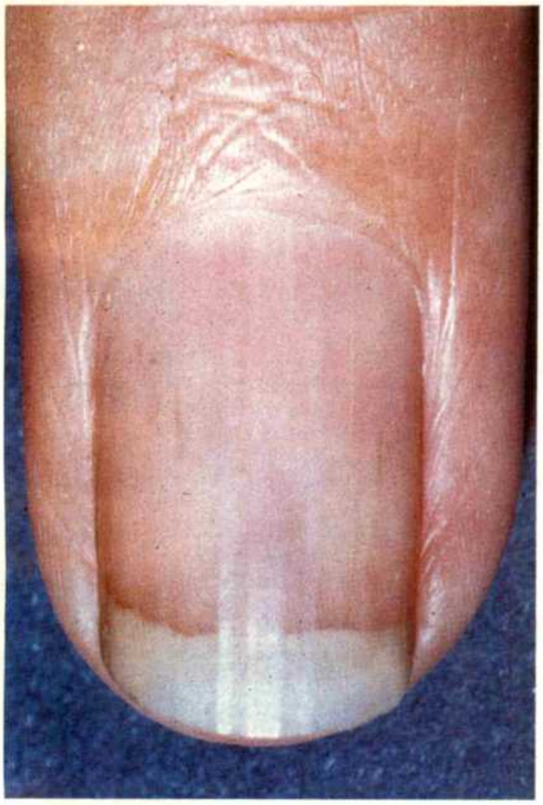

Figure 6 *A subungual glomus tumour seen through the nail, appearing as a bluish tinge beneath the central nail. The vague signs contrast markedly with the extreme symptom of pain*

Mucous cyst

A mucous cyst is not a true tumour but a collagenous degeneration of the extensor tendon of the distal interphalangeal joint. In the past it has been designated as a synovial cyst. The condition forms on the dorsum of the distal phalanx between the distal interphalangeal joint and the base of the nail, from where it tracks down to present as a brown or bluish swelling with distortion of the nail. It is usually quite small, but will eventually deform the nail. It frequently accompanies osteomyelitis of the adjacent joint. As soon as the nail is incised or removed, the colourless, glairy nature of the fluid, typical of that seen in a ganglion, is immediately obvious.

Subungual fibroma

This benign non-pigmented inactive lesion may be single or multiple. Subungual fibromas usually lie outside the nail, projecting from below the cuticle. Occasionally they arise under the nail plate and extend from the base of the nail to its tip.

Keratoacanthoma

Subungual keratoacanthoma is an infrequent, benign, but rapidly growing and aggressive tumour usually situated below the edge of the nail plate or in the distal portion of the nail bed[28]. Diagnosis of this condition depends on the rapid growth with bone destruction and characteristic histology. Its clinical differentiation from squamous cell carcinoma is difficult. Treatment consists of complete excision after removal of the overlying nail.

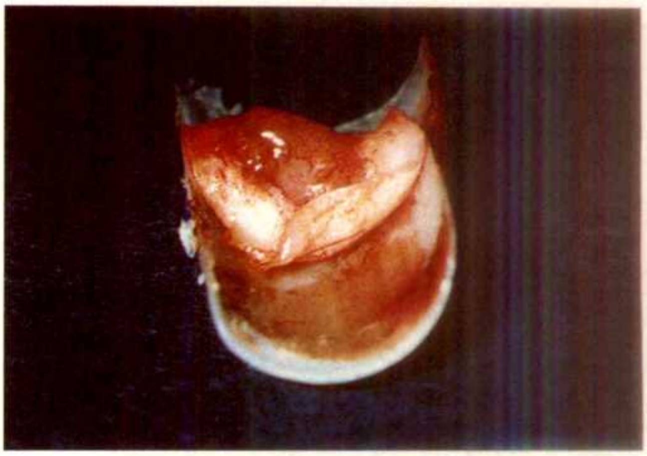

Figure 7 *The glomus tumour from* Figure 6, *lying on the underside of the nail matrix after its removal from a depression in the underlying bone*

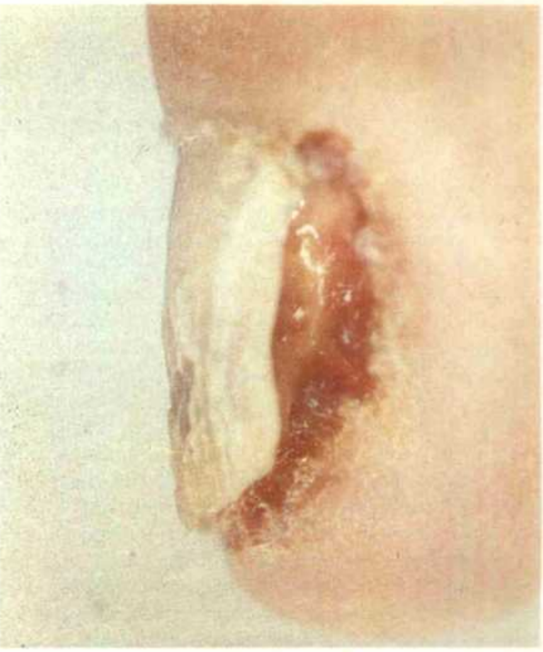

Figure 8 *Squamous cell carcinoma of the nail, treated first as a fungal infection. Histological diagnosis was made only after distal amputation; previous biopsies were reported as benign*

Bowen's disease

Bowen's disease of the nail unit presents as a slowly growing periungual, erythematous, squamous or eroded plaque. Involvement of the proximal nail fold results in the formation of a characteristic whitish band. The fingers are more frequently affected than the toes. The development of Bowen's disease is slow and should be suspected in any case of gradual destruction of a single nail in the absence of fungal infection. Biopsy often reveals invasive squamous cell carcinoma.

Subungual squamous cell carcinoma

This is a tumour of the nail sulcus rather than of the matrix, so it presents from under the distal end or lateral edge of the nail (*Figure 8*). It is such a slow growing tumour that it leads to a sense of false security. A history of 3–4 years is not uncommon[29]. Squamous cell carcinoma ulcerates more quickly than a subungual melanoma but, because it has such slow growth, it bleeds less readily. Complacency about the diagnosis is reinforced by the difficulty of pathological diagnosis. The tumour is frequently so well differentiated that a diagnosis of carcinoma cannot be made on cytological grounds: the pathologist may consider the condition to be pseudoepitheliomatous hyperplasia. It is sometimes necessary to proceed to local amputation on the grounds of presumptive clinical diagnosis supported by a pathological diagnosis of hyperplasia. The prognosis is, in general, good, so that a conservative amputation is often appropriate.

Management policy for cases of suspected subungual melanoma

A lesion that is very likely to be a haematoma

It is reasonable to watch this lesion for a short time, say 4–6 weeks, by which time it should be obvious that the lesion has grown out from the lunula. If this has not occurred, the lesion should be biopsied.

Early lesions that are considered to be naevi or early melanomas

These should be submitted to early biopsy. The easiest way to do this is by drilling a small hole in through the nail with a dental drill. This allows easy and painless access to the lesion to allow a specimen to be taken for cytology. The difference between haematoma and naevoid lesions is easily made on cytological examination, and if this shows abnormal cells it is best to proceed to formal biopsy by removing all or part of the nail.

More advanced lesions, where tissue is available for direct biopsy

Incision biopsy should be used in the first instance, using a gentle technique. We believe this to be less dangerous and less traumatic than removing the nail. If a small incision biopsy confirms the diagnosis of melanoma, one can proceed to appropriate amputation without deep or traumatic biopsy. Early subungual melanoma of a digit is satisfactorily treated by metacarpophalangeal or metatarsophalangeal amputation of the digit, although Papachristou and Fortner[30] suggest extension to the tarsometatarsal level. We advocate this where the nail is elevated or melanoma extends on to the nail fold[31].

We did not have a uniform policy for node dissection during our own, Cardiff experience. The high incidence of nodal deposits with melanoma of the digit would suggest a role for prophylactic node dissection. Therapeutic lymphadenectomy in the absence of systemic disease can be rewarding[32]. The low incidence of *in-transit* metastases from subungual melanoma has led us to reserve limb perfusion with a cytotoxic agent for overt recurrence. It is not possible to give authoritative guidelines on management, because the disease is so rare and no comparative studies of different methods of management have been reported.

Contralateral inguinal lymph node metastasis in patients with melanoma of the lower extremities

A. Jonk, B. B. R. Kroon, W. J. Mooi and C. A. Hoefnagel

Division of Clinical Oncology, The Netherlands Cancer Institute (Antoni van Leeuwenhoek Huis), Plesmanlaan 121, 1066 CX Amsterdam, The Netherlands

Correspondence to: Dr B. B. R. Kroon

A retrospective study was carried out on six patients with contralateral inguinal lymph node metastasis from a melanoma of the lower extremity. All six patients were found to have had a previous homolateral groin dissection and in five patients there was intercurrent disease relapse in the leg before or at the same time as the appearance of contralateral node metastasis. Although the prognosis in these patients is unfavourable, two had a survival period of 24 and 32 months and two were still alive 27 months after contralateral groin dissection. In order to determine possible pathways of dissemination, lymphoscintigraphic studies of the leg were performed in another 16 melanoma patients who in the past had undergone a groin dissection. In 13 of them uptake in the contralateral inguinal lymph nodes was detected, indicating that groin dissection can lead to a different lymphatic flow pattern, which is often directed to the contralateral groin. Contralateral lymph node involvement may be an expression of regional disease. In such patients a contralateral groin dissection is advocated.

Keywords: Contralateral inguinal lymph node metastasis, melanoma, lymphoscintigraphy

The clinical presentation of lymphatic spread in patients with a mprimary melanoma of the lower extremity is usually enlarged inguinal nodes on the homolateral side. In the course of the disease, some patients present with contralateral inguinal lymph node involvement. It is unclear whether these contralateral node metastases should be considered to be regional disease and whether locoregional treatment is beneficial.

A subset of patients with contralateral nodal spread after homolateral inguinal block dissection has been studied and the pathways of dissemination have been investigated.

Patients and methods

Patients with contralateral inguinal lymph node involvement

Between 1966 and 1986, of 132 patients treated for regional inguinal lymph node metastasis from melanoma of the lower extremity, six patients were seen with contralateral inguinal lymph node involvement. Three subjects were men and three were women, and their ages ranged from 18 to 69 years (mean 48 years). In two patients the primary tumour site was on the upper leg, in two on the lower leg, and in the other two on the foot. The Breslow thickness of the primary tumour ranged from 1·15 to 4·00 mm (median 2·95 mm). All patients were found to have had a previous homolateral groin dissection and in five patients there had been homolateral lymph node involvement. In all six patients a time interval existed between treatment of the primary tumour and that of the homolateral lymph nodes, varying from 2 weeks to 7 years. Contralateral lymph node involvement became clinically evident 2, 11, 20, 27, 80 and 132 months after homolateral groin dissection. One patient, in whom distant metastases were detected simultaneously with the appearance of contralateral lymph node involvement, received systemic treatment. Of the other five patients, one received radiotherapy to the contralateral nodes and four were treated by contralateral groin dissection. There was intercurrent disease in the leg, consisting of local recurrence and/or *in-transit* metastasis, in five patients, either at the time of homolateral groin dissection or between homolateral and contralateral groin dissection. The follow-up was complete in all patients.

Patients with lymphoscintigraphic evaluation

In order to detect possible pathways of dissemination, lymphoscintigraphic examinations were carried out in another group of 16 melanoma patients who previously had had a homolateral groin dissection. Lymphoscintigraphy of the operated leg was performed 1 year or more after dissection, using a dual head, large field of view γ camera connected to a computer system. Multiple digital images were made 1 h and 4–5 h after subcutaneous interdigital administration of 37 MBq (1 mCi) technetium-99m microcolloid, acquiring counts over 5 min in a 256 × 256 matrix. The scans were evaluated for lymphatic stream patterns in the leg and for uptake in the ilioinguinal and aortic lymph nodes on both sides as well as in the liver.

Results

Patients with contralateral inguinal lymph node involvement

At the time of analysis two patients were still alive, both 27 months after detection of contralateral lymph node involvement. However, both patients had distant metastases. The other four patients had died 4, 5, 24 and 32 months after detection of contralateral lymph node involvement. The two patients who survived for 24 and 32 months, as well as the two who were alive, had been treated with contralateral groin dissection. Disease-free intervals are shown in *Table 1*.

Patients with lymphoscintigraphic evaluation

In 15 of 16 patients in whom lymphoscintigraphic studies were performed no uptake of radioactivity was seen in the operative field. If any isotope activity was detected in the leg, it was observed to be on the medial side. Six patients showed a slow drainage pattern and, in these, isotope activity was seen mainly below the knee. These patients had developed lymphoedema of the leg after groin dissection. In four of these six patients the isotope uptake was clearly seen in the liver. In contrast, only one out of the ten patients with a good drainage pattern showed such a clear uptake in the liver. Medial bypassing of the operative field could not be detected. In nine of the ten patients with a good drainage pattern the operative area was laterally bypassed with filling of the lymph nodes alongside the homolateral common iliac artery and the aorta (*Figure 1*). In nine patients of the latter group, crossing over to the contralateral inguinal lymph nodes by way of a route proximal to the inguinal operative field was detected (*Figure 1*). This pattern of lateral bypassing and crossing over was also seen in four of the six patients with slow drainage.

Discussion

Previous studies of the lymphatic pathways in patients with inguinal lymph node metastases from a melanoma situated on

6	1·0	—	2·0	0·0

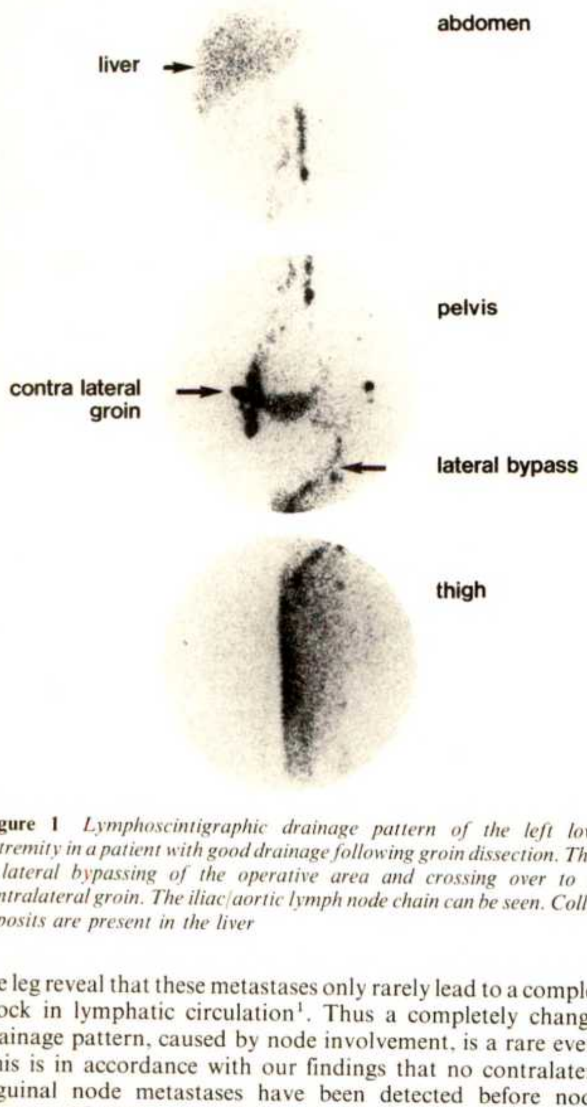

Figure 1 *Lymphoscintigraphic drainage pattern of the left lower extremity in a patient with good drainage following groin dissection. There is lateral bypassing of the operative area and crossing over to the contralateral groin. The iliac/aortic lymph node chain can be seen. Colloid deposits are present in the liver*

the leg reveal that these metastases only rarely lead to a complete block in lymphatic circulation[1]. Thus a completely changed drainage pattern, caused by node involvement, is a rare event. This is in accordance with our findings that no contralateral inguinal node metastases have been detected before nodal surgery. After lymphadenectomy, changing drainage patterns through pre-existing lymphatic connections have been described in patients with a trunk melanoma[2]. Our lymphoscintigraphic studies indicate that the same mechanism probably holds true for the observed crossing over phenomenon after homolateral groin dissection for melanoma of the lower extremity. Therefore, contralateral inguinal lymph node metastasis can result from lymphatic spread.

Remarkably, in our lymphoscintigraphic studies the drainage pathway to the contralateral inguinal lymph nodes was found to be lateral and proximal to the operative field. This pathway is probably subcutaneous, lateral to and proximal to the scar in the groin, and caused by an impaired lymph drainage after resection of the normal medial pathways in the inguinal and iliac/obturator region. The observation that no crossing over took place in two of six patients with slow drainage, compared with no crossing over in only one of ten patients with good drainage, may be explained by the fact that in this group the isotope supply to the groin was not sufficient to produce reliable images of the contralateral lymph nodes.

In our postoperative study an enhanced isotope uptake was seen in the liver of four lymphoedematous patients with slow drainage. An explanation for this finding might be that because of lymphatic obstruction lymphaticovenous shunting had developed, which is in accordance with observations from animal experiments[3].

In our study group of six melanoma patients with contralateral lymph node metastasis, five had an intercurrent limb relapse (local recurrence or in-transit metastasis). In the other patient no intercurrent disease was seen in the leg. The fact that distant metastases in this patient were detected simultaneously with contralateral lymph node metastases suggests that contralateral lymph node metastasis was the result of general dissemination. In the other five patients, distant metastases could not be detected at that time, but in all systemic disease developed later.

In conclusion, patients with contralateral lymph node involvement have a poor prognosis. Nevertheless, the results of our lymphoscintigraphic studies suggest that the disease in these cases may still be regional. In our opinion contralateral radical groin dissection in these patients is to be recommended.

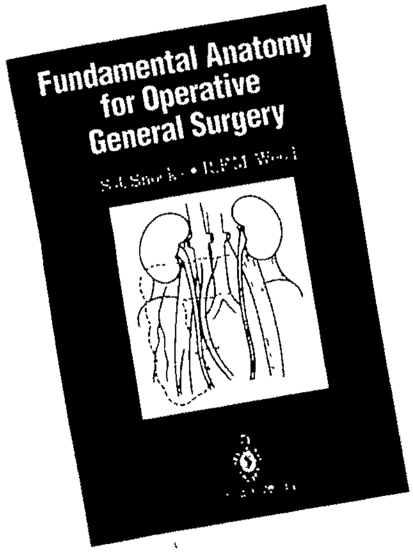
Fundamental Anatomy for Operative General Surgery



1989. VIII, 91 pp. 42 figs. Softcover £ 12.00 ISBN 3-540-19535-1

This is the first of a number of atlas-texts describing the essential anatomical basis of a range of common surgical procedures. Safe surgery is founded upon careful dissection and clear identification of vital structures. Knowledge of the appropriate anatomy and anatomical relations is therefore essential, not only during surgical training, but as the cornerstone of surgical practice. In these books, clear line diagrams facing each page of text illustrate the important features that have to be identified. They highlight for trainees and practising surgeons features of the operations which are important anatomically, but do not attempt to give a complete description of the surgical procedure.

Instructor's Note
If you are active in teaching, you can request an examination copy by writing to us using your departmental letterhead. Please include name of course taught, title of current text, and expected number of students.

NEW FROM BUTTERWORTHS

MANAGEMENT OF ABDOMINAL HERNIAS

H Brendan Devlin MA MD MCh (Dublin) FRCS(England) FRCS(Ireland) FACS
Consultant Surgeon, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

Management of Abdominal Hernias is the most comprehensive work to date on the subject. In this exhaustive volume the author discusses the historical background to hernia management and its influence on current practice.

The basic sciences and operative technique of hernia surgery are dealt with in practical terms and guidance on complications and postoperative care is supported by new data based on long term studies.

★ **the author is a leading authority on hernia management**

★ **extensively illustrated with high quality line drawings, half-tones and colour photographs.**

"This book is beautifully produced, clearly written and profusely illustrated, mainly by excellent line drawings. It would be of considerable value to the surgeon in training (who, in this country, is called upon to do the majority of this type of surgery) but it would also be read with interest by his Chief."

British Journal of Clinical Practice

"The anatomy of the abdominal wall is excellently set out and clearly described and I would recommend all surgeons in training, particularly at senior house officer level, to read it.

"This is a very readable and enjoyable book. It is not directed at any particular grade of surgeon but will inform and enlighten the majority of those who read it."

British Journal of Hospital Medicine

Early evaluation of anorectal myectomy in this unit suggested that it might provide clinical benefit to patients with outlet obstruction. Long term results of anorectal myectomy are now available in 63 patients operated on between February 1984 and February 1988 with a median follow-up of 30 months. Spontaneous rectal evacuation without the need for laxatives was recorded in only 11 patients (17 per cent), while 44 (70 per cent) achieved no functional improvement. Mild incontinence developed in 6 patients (10 per cent). Results were independent of preoperative colonic transit or histological evidence of aganglionosis.

Keywords: Constipation, anorectal myectomy, aganglionosis

An increasing number of chronically constipated patients are referred to coloproctologists for investigation and treatment. Two distinct groups of patients have been recognized. those with colonic inertia and those with outlet obstruction. Anorectal myectomy has been proposed as a method of diagnosing short segment Hirschsprung's disease and providing therapeutic benefit for outlet obstruction[1].

The purpose of this report is to record the longer term functional results of anorectomyectomy in a consecutive series of constipated patients.

Patients and methods

Anorectal myectomy was performed in 63 patients between February 1984 and February 1988. All had videoproctographic and electrophysiological evidence of outlet obstruction The mean age was 37·0 years (range 14–70 years) and all except five patients were women. The diagnosis of outlet obstruction was based on the following findings: (1) patients were unable to expel a 100 ml balloon from the rectum; (2) increased electrical activity in the puborectalis during attempted defaecation; (3) an inability to open the anorectal angle and evacuate contrast during the videoproctography. None of the patients had radiological evidence of megarectum but the rectoanal inhibitory reflex was absent in nine patients.

The patients were seen at regular intervals after the operation with a median follow-up of 30 months (range 12–59 months). Results were assessed by frequency of spontaneous defaecation without the use of laxatives, freedom from straining and alleviation of abdominal pain and distension. An overall response was judged as satisfactory, bowels opened regularly without laxatives and no other symptoms; improved, some improvement, but laxatives still required and occasional distension or abdominal pain; poor, no improvement at all

All myectomy specimens were sent for histology, and the presence or absence of ganglion cells determined Twenty-nine patients had anal manometry studies performed by a closed water filled balloon probe before, 3 months and between 12 and 24 months after operation.

Results

Operative morbidity

An intersphincteric abscess developed postoperatively in four patients but in each case the sepsis resolved without functional impairment of continence. Three patients had transient incontinence of flatus after operation and three other patients had persistent minor faecal incontinence.

Functional results

Forty-four patients (70 per cent) obtained no long term benefit from the operation (*Table 1*) and only 11 now consider that rectal evacuation is near normal. Temporary improvement was observed in 31 patients when they were first assessed 8–12 weeks after operation but this was sustained in only 19 when reviewed after 6–12 months. Nineteen patients (30 per cent) later underwent subtotal colectomy because of persistent constipation. There was no correlation between delayed transit time (fewer than 80 per cent of markers passed in 5 days) and outcome of anorectal myectomy (*Table 2*).

Histology

Absence of ganglion cells in the anorectal myectomy specimen 2 cm above the dentate line was found in 12 patients. There was no correlation between aganglionosis and outcome (*Table 3*).

Manometry

The preoperative median (range) resting and squeeze pressures were 129 cmH_2O (87–162 cmH_2O) and 187 cmH_2O (164–339 cmH_2O), at 3 months the values were 106 cmH_2O (69–154 cmH_2O) and 162 cmH_2O (130–354 cmH_2O) and at 12–24 months they were 117 cmH_2O (67–169 cmH_2O) and 177 cmH_2O (139–366 cmH_2O). The only significant change was the transient fall in resting pressure 3 months after operation

Table 1 *Functional results* (n = 63)

Overall	
Satisfactory	11 (17)
Improved	8 (13)
Poor	44 (70)
Bowels opened spontaneously without laxatives	
At least three times per week	14 (22)
Less than three times per week	6 (10)
Laxatives taken	43 (68)
Straining on defaecation	
Absent	6 (10)
Present	57 (90)
Abdominal pain and/or distension	
Absent	16 (25)
Present	47 (75)

	Normal ($n=45$)	Aganglionosis ($n=12$)*
Satisfactory	7 (16)	2 (17)
Improved	5 (11)	3 (25)
Poor	32 (71)	7 (58)

Values in parentheses are percentages; * histology not available in six patients

Discussion

Anorectal myectomy was first described for the diagnosis and treatment of short segment Hirschsprung's disease[2,3]. Later Martelli *et al.*[1] introduced anorectal myectomy as a surgical option for the treatment of idiopathic constipation. Results in patients with anorectal (outlet) obstruction were spectacular: 62 per cent were reported as cured with a further 15 per cent who were improved. These patients had abnormal transit time but there was no videoproctographic or electromyographic assessment.

We reported encouraging results in the first 29 patients of the present series, and 4 months after operation 62 per cent of patients achieved a bowel frequency of at least three stools per week without laxatives[4]. However the assessment only recorded bowel frequency. The results of this long term review demonstrate only a transient improvement associated with a temporary reduction in resting anal canal pressure. This operation is thought to be useful as a method of excluding aganglionosis. An aganglionic segment was found in 12 of 57 cases (21 per cent), similar to the 22·5 per cent reported by Martelli[1]. It has been suggested that the procedure might be most beneficial for patients with short segment Hirschsprung's disease, but our data do not support this theory. Indeed there is some doubt about the clinical entity of short segment Hirschsprung's disease, since the autonomic innervation of the distal anal canal is a variable in normal subjects and there appears to be no correlation between manometry and aganglionosis.

Frequency of defaecation has been used to assess the outcome of operation. However, the presence of abdominal symptoms, the irregular use of laxatives and the emotional instability commonly found in these patients[5] render the number of bowel evacuations an unreliable parameter for evaluation. It would be more appropriate to consider this abnormality as a complex functional bowel disorder apparently unrelated to dietary fibre[6]. Attempts to classify these patients into those with slow colonic transit (colonic inertia) or outlet obstruction, although attractive, has not always proved helpful. The so-called 'paradoxical contraction'[7] of the puborectalis and the disordered flap-valve theory[8,9] have been largely discredited since there has been no therapeutic benefit from division of the puborectalis[10–12]. The high recurrence of abdominal symptoms after subtotal colectomy indicates that colonic transit is not the only physiological disorder in these patients[13]. Failure to demonstrate anatomical or histological evidence of a pelvic floor abnormality in a high proportion of patients suggests that severe constipation is often a psychologically induced functional disorder. The clinical result of this condition is often identified as an inability of the external sphincter and puborectalis to relax during defaecation, currently termed anismus[14]. Attempts have been made to reverse this physiological abnormality by local neuromuscular blockade[15], but the deep-rooted psychological nature of this condition suggests that pharmacological therapy alone may be associated with disappointing results. Bleijenberg and Kuijpers[16] have proposed an interesting treatment for both the physical and mental components of this syndrome.

In view of the risk of mild incontinence in six of 63 patients treated by anorectal myectomy (10 per cent) taken with the disappointing long term results, this operation, even as a diagnostic procedure, can no longer be recommended for chronic constipation.

Detection of lymph node metastases in colorectal carcinoma before and after fat clearance

One hundred and three colorectal carcinoma specimens were examined to determine the value of the xylene and alcohol fat clearance technique in detecting lymph node metastases. The mesocolon or mesorectum was dissected initially by the traditional method and all the lymph nodes identified were examined histologically. After fat clearance the specimen was dissected again and further lymph nodes were examined. Forty-one specimens were obtained from the rectum and 62 from the colon. Traditional dissection produced a mean of 6·2 lymph nodes per specimen, but following fat clearance a further mean of 12·4 nodes per specimen were found. The total number of lymph nodes recovered varied from two to 69 with a mean of 18·5 per specimen. Traditional dissection showed 45 specimens (43·7 per cent) to have lymph node metastases but after fat clearance a further five specimens (4·8 per cent) were found to be lymph node positive. Therefore, of the 58 specimens graded initially as Dukes' B, five (8·6 per cent) were shown after fat clearance to be Dukes' C tumours. In the Dukes' C cases the mean (s.d.) number of involved lymph nodes per specimen was 2·7 (2·1) by traditional dissection and 4·2 (3·9) after fat clearance. Forty-seven (94·0 per cent) of the Dukes' C tumours were correctly identified after examination of specimens containing up to 13 lymph nodes. Fat clearance of the mesocolon or mesorectum should be used when traditional dissection has failed to identify at least 13 nodes and the tumour has been classified as Dukes' B.

Keywords: Dukes' classification, lymph node metastases, xylene and alcohol fat clearance

Dukes' classification[1] remains the single most important factor when considering the prognosis in colorectal cancer. In order to classify a tumour accurately many lymph nodes should be examined histologically and the presence or absence of metastases noted. The number of lymph nodes with metastatic deposits[2], and the involvement of the apical nodes, have also been shown to have prognostic significance[3,4]. To determine the effect of adjuvant therapy in colorectal carcinoma it is important to distinguish accurately a Dukes' B from a Dukes' C tumour[5]. Blenkinsopp *et al.*[6] highlighted the wide variation in both the number of lymph nodes identified and the number of lymph nodes shown to contain metastases.

In an attempt to improve the harvest of lymph nodes the technique of fat clearance using xylene and alcohol has been developed[7,8]. Cawthorn *et al.*[8], in a trial of adjuvant preoperative radiotherapy for rectal cancer in Guildford, UK, used this technique. They identified a significantly greater number of nodes in the mesorectum than St. Mark's Hospital and seven other centres in the same study which did not use the clearance technique. Their study also identified a greater number of lymph nodes with metastases in cleared compared with non-cleared specimens.

In contrast, Jass *et al.*[7] found no significant difference in the number of lymph nodes harvested when traditional dissection and fat clearance methods were compared, but the mean time taken for traditional dissection in this study was 23 min. The present study was undertaken to compare the traditional dissection method and the fat clearance technique as applied to the same specimens, with the one technique following the other. An attempt was also made to determine the minimum number of lymph nodes which need to be examined to provide an accurate assessment of the presence of nodal metastases.

Materials and methods

All the specimens of colorectal cancer which were resected over a 1-year period were included in the study. The specimens were from 15 right hemicolectomies, three transverse colectomies, eight left hemicolectomies, 26 sigmoid colectomies, 28 anterior resections and 23 abdominoperineal resections. Most resections were carried out by one surgeon The ligature of the inferior mesenteric vessels was not necessarily 'high' for rectal cancer, but the pararectal dissection was always low and wide[9]

Opened specimens of colon or rectum were received in formalin and allowed to fix overnight. On the following day the mesocolon or mesorectum was dissected from the posterior aspect of the bowel and blocks were taken for histological section from the primary tumour in the normal way The fat of the mesocolon or mesorectum was carefully dissected by routine slicing and a single block was taken from all the lymph nodes found, whether they appeared to be involved by tumour or not. These lymph-node blocks were processed in the normal manner and a count was made of the total number recovered and the number involved by secondary tumour Approximately half of each node was removed and the remainder was left in the specimen

The mesocolon or mesorectum was then placed intact in a bath of alcohol (100 per cent) and kept there for approximately 1 week, the alcohol was changed every day during this period. The specimen was then placed in neat xylene and left there for approximately 2–3 weeks with several changes of xylene during this time Three weeks later the specimen was examined to see whether the fat had cleared, and if it had not it was placed in xylene for a further week. A fully cleared specimen could be examined in a fume cupboard using back lighting Any lymph nodes found, which had not previously been sampled, were taken for histological examination. It was possible to identify previously sampled nodes because these had been cut through at the first examination. A count was then made of the additional number of lymph nodes recovered at the second examination. A single block was again taken from each node and examined histologically for the presence of tumour deposits.

0007-1323/89/1165-03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Tumours in the Dukes' C category were not subdivided into C_1 and C_2 in this study.

Results

One hundred and three specimens of colorectal carcinoma were examined. The sites of the tumours and the mean numbers of lymph nodes found by traditional dissection followed by fat clearance are shown in *Table 1*. The total number of lymph nodes recovered, irrespective of whether they were involved by tumour or not, ranged from two to 69 with a mean value of 18·5 per specimen. The distribution pattern is shown in *Figure 1*. The median value was 16·6 for the 103 cases examined and 16·8 for the 41 rectal cases. The mode for the 103 cases was 13·0 and that for the 41 rectal cases was 12·4. A small number of specimens had a very large number of nodes (more than 45 per specimen). The mean number of nodes found in specimens from the upper rectum was 23, compared with 18 from the midrectum and 15 from the lower rectum.

Forty-five specimens (43·7 per cent) were found to have lymph node metastases by the traditional dissection method. After fat clearance five further specimens (4·8 per cent) were found to have node involvement making a total number of 50 Dukes' C cases (48·5 per cent). Of these five tumours, one was located in the right colon, two in the descending colon and two in the rectum.

The mean (s.d.) number of involved lymph nodes identified by traditional dissection in Dukes' C specimens was 2·7 (2·1) but this increased to 4·2 (3·9) when nodes identified by fat clearance were included. The presence of an increased number of involved nodes was found in 24 specimens. The comparable figures for Dukes' C specimens from the rectum only were 2·7 (2·1) and 4·8 (4·6).

In order to determine the minimum number of lymph nodes which require to be examined histologically to provide an accurate estimate of the presence or absence of metastases, the 50 Dukes' C cases were considered separately. As the total number of lymph nodes examined increased, the cumulative percentage of specimens with nodal metastases also increased (*Figure 2*). Twenty-six (52 per cent) of the Dukes' C tumours were identified by the examination of specimens containing up to six lymph nodes A further 21 Dukes' C tumours were identified by examination of the specimens which contained between seven and 13 lymph nodes; therefore, 47 (94 per cent) of the C tumours were identified after examination of the specimens in which up to 13 lymph nodes were found. The remaining three tumours in the C group were found in specimens which had 15, 18 and 21 lymph nodes respectively.

Discussion

Previous studies using the xylene and alcohol fat clearance technique[7,8] have been applied to rectal tumours. In this study all colorectal cancers were included but there was no difference in the effects of fat clearance when comparing varying primary tumour sites. Fat clearance yielded increased numbers of lymph nodes, from all specimens, when compared with traditional dissection. Cawthorn *et al.*[8] identified a mean number of 23·1 nodes per specimen in the mesorectum of patients with rectal primary tumours, using the fat clearance technique. They compared this with 13·1 nodes identified by the prolonged traditional dissection at St. Mark's Hospital and 10·5 nodes found at seven other 'non-cleared' centres, concluding that the clearance technique identified a greater number of nodes in the mesorectum. In this study an average of 6·1 nodes per specimen were identified by traditional dissection in the mesorectum of the 41 cases of rectal carcinoma, but following fat clearance a total of 18·9 nodes per specimen were found. This study therefore supports the findings of Cawthorn *et al.*[8] that the fat clearance technique is of use in increasing the yield of lymph nodes from the mesorectum rather than the conclusions of Jass *et al.*[7] who found no significant difference between the two techniques. Further the increased yield of lymph nodes applied to specimens from all areas of the colon. This study shows that different individuals have a widely different number of nodes, irrespective of whether they are involved by secondary tumour or not.

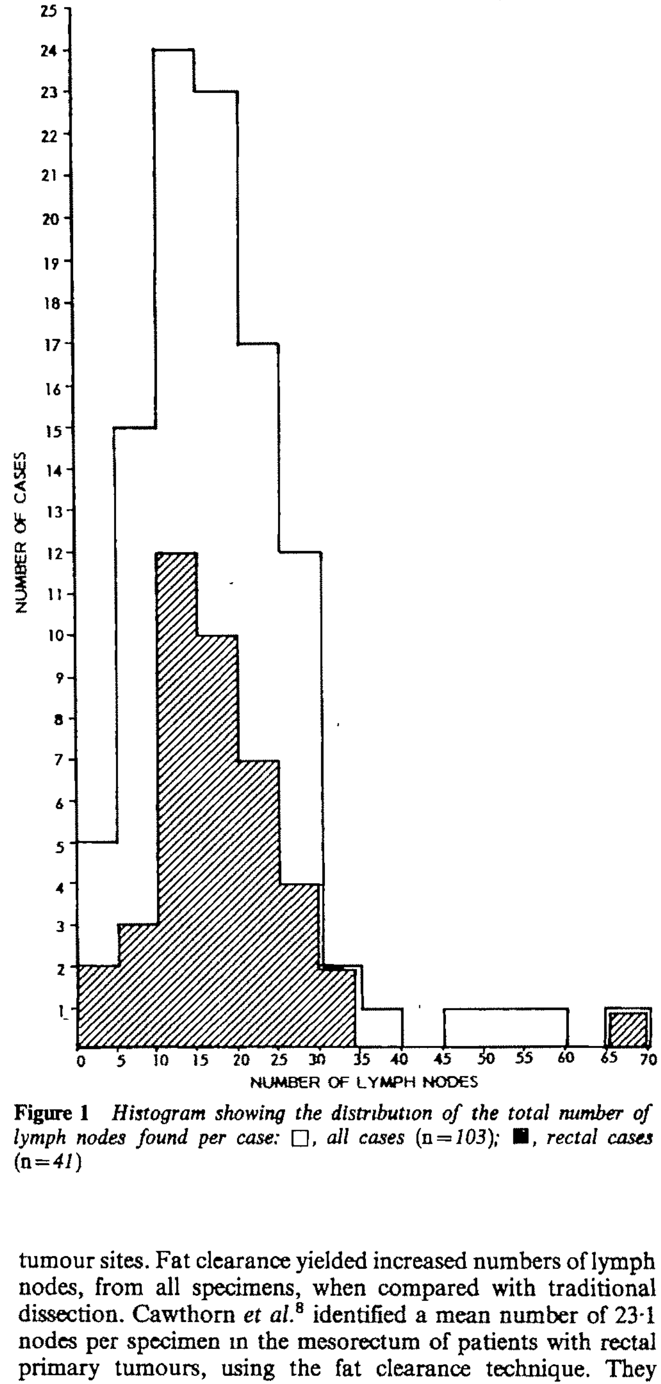

Figure 1 *Histogram showing the distribution of the total number of lymph nodes found per case:* □, *all cases* (n = *103*); ■, *rectal cases* (n = *41*)

Table 1 *Site of primary tumours and numbers of lymph nodes identified by both techniques*

Tumour site	Number of cases	Number of lymph nodes identified*		
		Traditional dissection	Fat clearance	Total
Right colon	15	9 6 (8·8)	11 3 (7·1)	20 9 (13·4)
Transverse colon	3	4 3 (1·5)	6·3 (9·3)	10·9 (9 3)
Left colon	8	4·5 (2·2)	13·4 (7·3)	17·9 (9·1)
Sigmoid colon	26	5 2 (4·5)	13 2 (8·4)	18 5 (10·2)
Rectosigmoid	10	5 4 (3·1)	11 4 (7 2)	16 7 (8 5)
Rectum	41	6·1 (4·3)	12·7 (8·1)	18·9 (10·9)
Total	103	6 2 (5·1)	12 4 (7·9)	18 5 (10 7)

* Mean (s.d.)

The increase in number of Dukes' C cases from 43·7 to 48·5 per cent following fat clearance is in agreement with Cawthorn *et al.*[8], who found 53 per cent of C tumours in fat cleared specimens compared with 50 and 48 per cent in the two

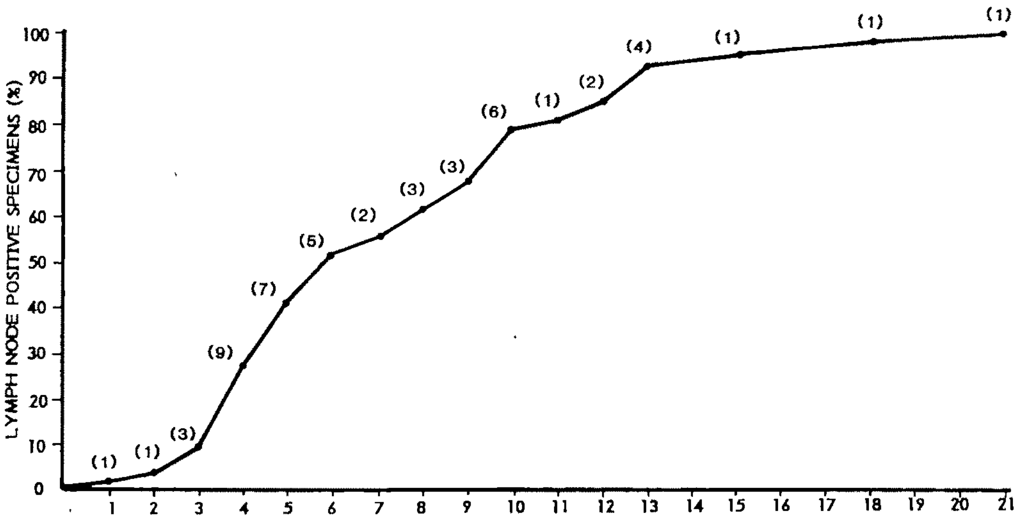

Figure 2 *The total number of lymph nodes recovered from each specimen compared with the cumulative percentage of specimens which had lymph node metastases. The figures in parentheses are the actual number of specimens which yielded the given number of lymph nodes*

'non-cleared' groups. They concluded that this was not a significant difference and the same is true of the present series. However when only the Dukes' B tumours are considered 8·6 per cent were incorrectly classified before fat clearance examination. The number of lymph node metastases found in the present study could still be an underestimate as Wilkinson and Hause[10] have shown that taking several blocks, rather than just one, from any one node can reveal an increased number of nodal metastases. The two stage technique, on one specimen, used in this study produced similar results to that of Cawthorn *et al*[8] who applied the two techniques to different specimens and compared the results from the different groups.

In addition to demonstrating an increase in the number of specimens which have nodal metastases following fat clearance, this study has also confirmed that in Dukes' C specimens fat clearance yields an increased number of nodes which contain metastases. Fat clearance therefore gives a more accurate estimate of the amount of tumour bulk contained in any given specimen of mesocolon or mesorectum.

This study has also established that the more lymph nodes which are examined the more accurate the detection of metastatic deposits. Obviously by the time all the nodes in a specimen have been examined staging can be made with complete accuracy, but there has been long debate on the minimum number of nodes which require to be examined to give a realistic assessment. From the present study it appears that if at least 13 lymph nodes are examined histologically then more than 90 per cent of the specimens which contain nodal metastases will be identified. As the fat clearance technique is unpleasant and time consuming, it is reasonable to suggest that all specimens of mesocolon or mesorectum initially reported as showing no nodal metastases after traditional dissection should undergo fat clearance and further examination if less than 13 lymph nodes were originally recovered.

Professor N. S. Williams

Fourteen patients with ulcerative colitis underwent formation of an S ileal pouch and construction of a stapled pouch–anal anastomosis by a modified technique, which eliminated the use of purse-string sutures. Eleven have had their covering ileostomies closed. Anal manometry performed before and a median of 9 months after ileostomy closure showed significant impairment of internal anal sphincter function. Night evacuation was significantly reduced in the stapled group compared with a similar group of patients who had undergone S ileal pouch formation, mucosal proctectomy and manual transanal anastomosis, but this was the only parameter of function to show a difference. A stapled pouch–anal anastomosis may be superior to the conventional procedure but it still may lead to internal anal sphincter damage which cannot be due to mucosectomy or prolonged anal retraction.

Keywords: Pelvic ileal pouch, anal manometry, bowel function, stapled anastomosis

The operation of mucosal proctectomy and pelvic ileal pouch formation has rapidly become an established technique for the surgical treatment of ulcerative colitis and familial adenomatous polyposis[1]. Indeed in most centres which specialize in coloproctology, the operation is now the procedure of first choice for most patients with ulcerative colitis. Despite the success of the procedure, there remain certain problems. The operation is technically demanding and requires a considerable learning period. Although most patients are continent for most of the time, many leak both mucus and faeces intermittently and particularly at night. The average number of bowel actions gradually decreases in time, but in most series six per 24 h seems to be the norm[2]. Some patients also complain of urgency of defaecation similar to that experienced while they had their disease. These defects in bowel function may in part be explained by the damage inflicted on the internal anal sphincter[3–5]. It is widely believed that this damage is caused by the mucosectomy itself together with the wide anal retraction required to achieve it. In order to simplify the technique and prevent damage to the internal anal sphincter we, like others[6,7], have used a stapling technique to effect the pouch–anal anastomosis. By eliminating the mucosectomy and the consequent anal retraction we hoped to prevent damage to the internal anal sphincter which occurs during the conventional operation. In order to simplify the stapled pouch–anal anastomosis we have modified our technique to eliminate the need for purse-string sutures[8].

Patients and methods

The operative technique (Figures 1 and 2)

Colectomy (if not performed previously), mobilization of small intestine and perimuscular dissection of the rectum were performed in an identical manner to the conventional operation[9], but the dissection of the rectum was continued down to the pelvic floor. Division of the anococcygeal attachment allowed the rectum to be lifted forwards between the two levator ani muscles. The rectum was strongly retracted upwards and a transverse stapling instrument was applied across the lower rectum at the level of the levator ani muscles. The new Roticulator 30® stapler (US Surgical Corporation and Auto Suture UK, Ascot, UK) was ideal for this manoeuvre because of its flexible head which could be angled on the instrument's shaft. Before the stapler was fired, the perineal assistant placed his index finger in the anorectum to determine the length of anorectum remaining. In most patients the proposed level of transection was found to be 1–2 cm above the dentate line. The stapler was fired and a right angled clamp was placed approximately 1 cm above it, the rectum was excised in the usual way.

A triplicated ileal pouch was then constructed from the terminal ileum using 15-cm limbs but with no efferent spout. The pouch was constructed in two layers using manual sutures but leaving the middle part of the anterior suture line unfinished for the later insertion of the EEA® anvil (US Surgical Corporation and Auto Suture UK). The anastomosis was effected without using purse-string sutures and this was most readily accomplished by using the Premium CEEA® (US Surgical Corporation and Auto Suture UK), although the conventional EEA was also used in some patients.

The cross-stapled top of the anal canal was pierced by the trocar point attached to the instrument shaft, while the anvil piece was taken separately and inserted into the lumen of the pouch through the unfinished anterior suture line. The latter was guided to the base of the pouch which was punctured by the pointed end of the anvil shaft well away from the suture lines. The trocar was then removed and the anvil shaft was pushed into the main instrument shaft to connect the gun, the gun was approximated and fired, establishing the anastomosis. A covering loop ileostomy was constructed in the usual way.

Patients

Between 1987 and 1988, 14 patients with ulcerative colitis underwent this procedure, nine of whom had previously had their colon excised. Eleven patients had their ileostomies closed and were available for study: there were six men and five women of median age 31 years (range 17–53 years).

Anal manometry was performed, using standard balloon manometry with a station pull through technique[10], in ten patients before the operation and at a median of 9 months (range 1–14 months) after the operation. Eight patients were studied between 6 and 14 months after ileostomy closure but two were studied at 1 and 3 months respectively. Of these two, one patient had his pouch removed because of continued pelvic sepsis and the other refused further investigation. Maximum basal anal pressure and maximum achieved pressure were measured. Maximum squeeze pressure was calculated as the maximum squeeze increment found on subtraction of basal pressures from achieved pressures.

Ten of the 11 patients were assessed clinically at 12 months after ileostomy closure. The patient who had his pouch removed was assessed at 1 month. Assessment was by a detailed clinical questionnaire completed by the interviewer, who was a surgeon who had not personally been involved in the patients' care. Questions that related to the patients' postoperative bowel function included day and night frequency, the degree of difficulty in evacuation, feeling of incomplete evacuation, continence, use of constipating drugs and the overall effect of the operation on the patients' social activities.

The clinical results were compared with 12 patients who had previously undergone mucosal proctectomy and ileal S pouch–anal

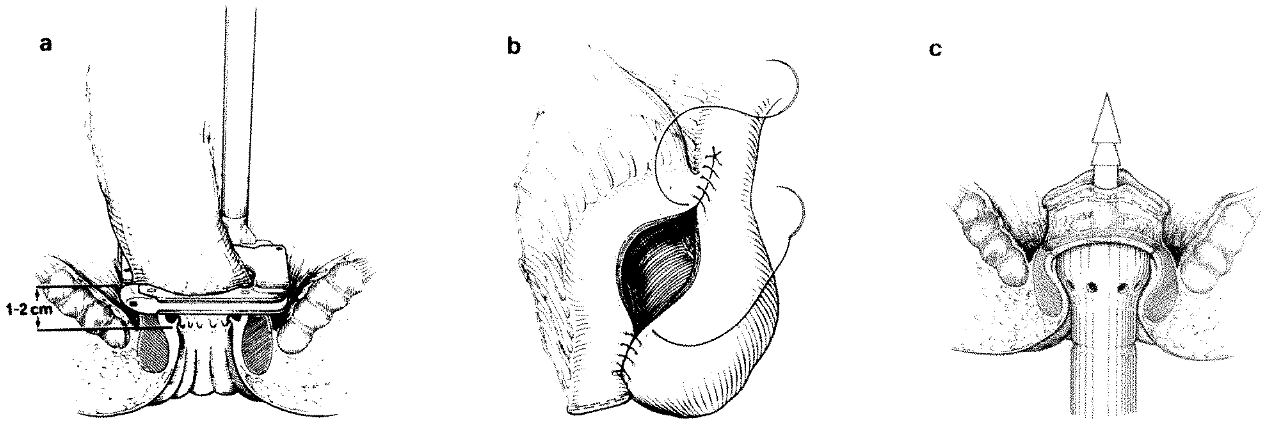

Figure 1 *The operative technique:* **a** *rectal transection at the level of the pelvic floor using the Roticulator 30 stapler;* **b** *S pouch formation leaving a defect in the anterior suture line;* **c** *the stapled top of the anal canal is pierced by the trocar of the Premium CEEA*

anastomosis by the standard manual technique. The two groups were similar with regard to age and sex distribution but the median time since operation was 6 months in the transanal group.

Statistical analysis

The Mann–Whitney *U* test was used to compare preoperative and postoperative basal and squeeze pressures. The χ^2 test with Yates' correction was used to analyse the significance of the difference in function between the patients with stapled and manual anastomoses.

Results

Morbidity and mortality

There was no mortality. The morbidity for all the 14 patients who underwent a stapled pouch–anal anastomosis is listed in *Table 1*.

Manometry

The mean (range) maximum basal anal pressure was 75 cmH_2O (52–110 cmH_2O) preoperatively; this decreased significantly to 34 cmH_2O (20–60 cmH_2O) postoperatively ($P<0{\cdot}01$; *Figure 3*).

The mean (range) maximum squeeze pressure was 140 cmH_2O (26–350 cmH_2O) preoperatively; this decreased to 93 cmH_2O (14–190 cmH_2O) postoperatively (n.s.; *Figure 4*).

Exclusion of the results of the two patients who were studied at 1 and 3 months after ileostomy closure did not change the statistical differences.

Clinical function

Stapled pouch–anal anastomosis (*Table 2*). Seven patients (64 per cent) had perfect continence, two patients (18 per cent) experienced occasional night leakage, once a week or less, one

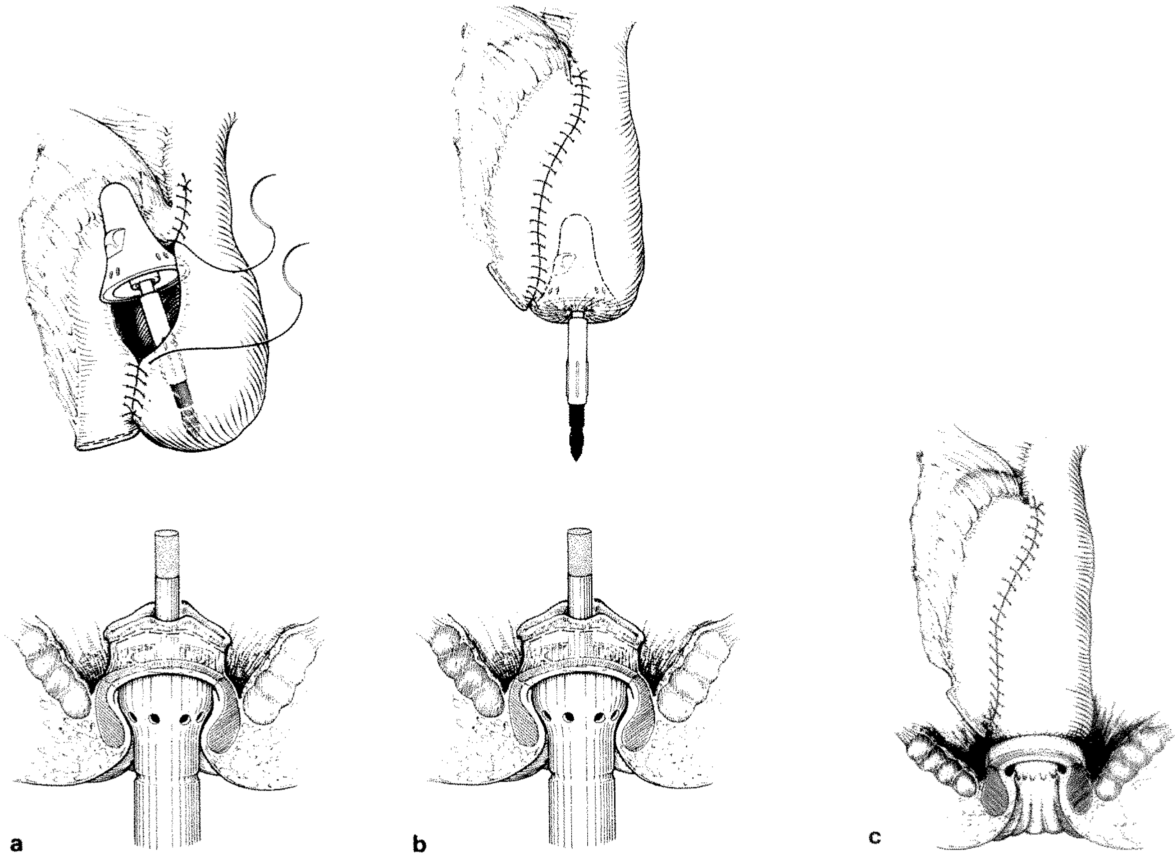

Figure 2 **a** *the anvil is inserted into the pouch through the unfinished anterior suture line and pushed through the base of the pouch and the trocar is removed from the instrument;* **b** *the anvil is pushed into the Premium CEEA gun shaft after the anterior suture line of the pouch has been completed;* **c** *the anastomosis is completed after firing the Premium CEEA and the gun is withdrawn*

Pouch–vaginal fistula	2
Postoperative pancreatitis	1
Stricture needing repeated dilatation	2
Wound infection	1
Acute pouch dilatation	1

*11 had ileostomy closed; †1 required removal of the pouch; ‡5 patients affected *in toto*

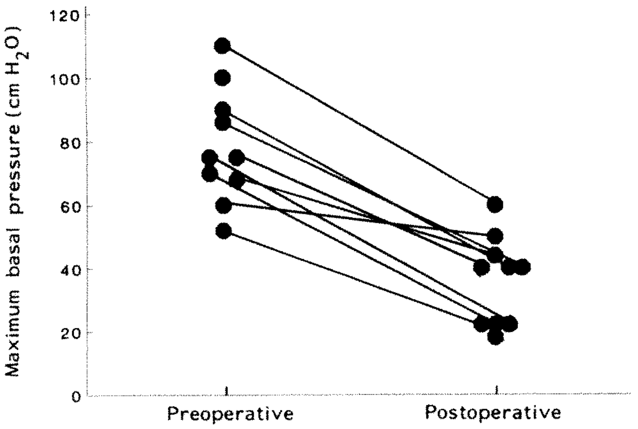

Figure 3 *Maximal basal anal canal pressure before and after stapled pouch–anal anastomosis. The postoperative values are significantly different from the preoperative values* ($P<0.01$)

patient (9 per cent) leaked small quantities every night and one patient (9 per cent) had major faecal leakage day and night. The median number of bowel actions during the day was six (range 2–15); the median number of nocturnal bowel actions was 1 (range 0–5), but only five of the 11 patients (45 per cent) had any night evacuations. Nine patients (82 per cent) had spontaneous evacuation, the remaining two patients (18 per cent) could evacuate spontaneously but, because they emptied their pouches incompletely, they were advised to intubate their pouches regularly. Eight patients (73 per cent) felt completely empty after defaecation. Eight patients (73 per cent) needed to use constipating drugs to control their stool frequency and four patients (36 per cent) needed to adjust their diet. Nine patients (82 per cent) led a completely normal life in terms of return to work and social activities.

Comparison with conventional manual anastomoses (*Table 2*). The retrospective comparison with patients who had undergone conventional transanal hand-sewn anastomoses shows no difference in most respects, apart from a significant decrease in night evacuation in the stapled group ($P<0.01$).

Discussion

The last decade has seen a revolution in the surgical treatment of ulcerative colitis. By use of mucosal proctectomy and pelvic pouch formation, a permanent ileostomy is avoided, the disease is eradicated and gastrointestinal continuity and continence is restored. The challenge that remains is to restore function to as near normal as possible.

Several important lessons have been learnt. An early problem with Parks' original S pouch was that 50 per cent of patients failed to empty the pouch spontaneously[11]. This was due to the length of the efferent spout[12], and its reduction to less than 2 cm has virtually eliminated the problem[2,12,13]. It was also realized that the length of anorectum required to be denuded of mucosa could be reduced from 10–12 to 4–5 cm without impairment of function and with a concomitant reduction in sepsis[14]. Another important lesson has been that patience by both patient and surgeon is required during follow-up, as function improves with time[2]. Similarly, it has been appreciated that function is positively correlated with the compliance and capacity of the pouch, hence the enthusiasm for larger volume pouches[13,15]. Despite these improvements there is still an appreciable number of patients who leak mucus or faeces or both, particularly at night. Also some patients experience an urgency of defaecation which is similar to that experienced before operation. These functional disturbances in part seem to be due to damage to the internal anal sphincter. Most workers who have performed manometry on their patients before and after surgery or have compared them with a control group have found that internal anal sphincter function has been compromised[3–5]. Further, this has not been a temporary defect, as resting anal pressure has remained low even after a 12 month period[3,15]. It has been assumed that this defect is due to direct trauma to the internal anal sphincter during removal of the mucosa and during prolonged anal retraction which is necessary in order to gain access for this manoeuvre. Indeed Keighley and his colleagues have demonstrated that function can be markedly improved if the mucosectomy is performed entirely from above without anal retraction[16].

The stapling technique was devised mainly to reduce internal sphincter damage by the elimination of the mucosectomy and the need for anal retraction. Surprisingly, this thesis has not been proved because there was a significant reduction in resting anal pressure. It is interesting to note that the experience of Johnston *et al.* with a similar stapling technique showed a

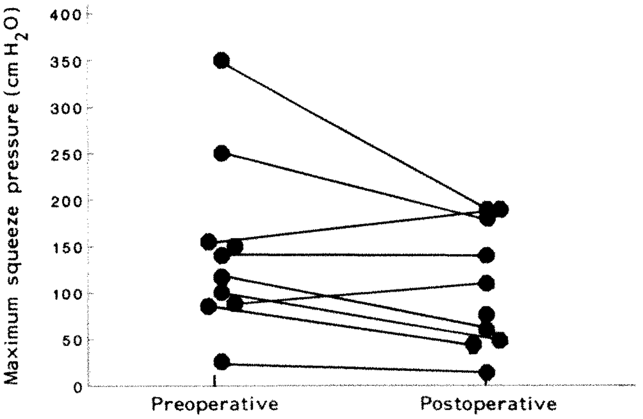

Figure 4 *Maximal squeeze anal canal pressure before and after stapled pouch–anal anastomosis. There is no significant difference between preoperative and postoperative values*

Unrestricted social life	9/11 (82)	9/12 (75)

Values in parentheses are percentages. * $P<0.01$ (stapled *versus* conventionally hand-sewn anastomoses) reduction in maximal resting anal pressure indicative of internal anal sphincter damage[7]. However, this reduction was less pronounced than that which has occurred in the present study.

It is difficult to explain why in our hands the stapled anastomosis produces such damage to the internal anal sphincter. It must be assumed that the brunt of the injury is due to the dissection and mobilization of the anorectum which may damage the extrinsic autonomic nerve supply which plays such an important part in internal sphincter function[17]. Also the transection of the rectal wall, at the level of the levator ani muscles, may cut through the layer of specialized circular muscle which forms the internal anal sphincter. The damage so inflicted will involve the intramural nerve plexus and blood supply as well as the muscle itself. Whereas a transection at a higher level is unlikely to produce direct damage to the internal sphincter, at this lower level such damage is presumably inevitable. Differences in results between series may therefore be related to the depth of anorectal dissection and the level of transection. It is of interest to note that there was also a fall in the squeeze pressures and, although this was not a statistically significant reduction, it suggests that the technique may in future be found to inflict similar damage on the external anal sphincter. No doubt sphincter damage could be avoided if the mobilization and transection of the rectum was not carried out to a low level, yet this would leave more than the 1–2 cm of anorectal mucosa, and such a policy would increase the risk of cancer development. As it is, this risk must be slightly greater than after the complete mucosal excision achieved during conventional mucosectomy. However such a small area is easily accessible by both digital and sigmoidoscopic examination and should not pose difficulties for assessment. Nevertheless strict surveillance of these patients will be necessary.

Despite the impairment of anal sphincter activity, bowel function after the operation appears satisfactory and marginally superior in the stapled group compared with that achieved after the conventional operation. Certainly night evacuation was significantly reduced. The modified stapling technique was also devised to avoid the use of purse-string sutures, and eliminate the concomitant problems[8]. It ensured that complete 'doughnuts' of tissue were obtained in each patient. It remains to be seen whether the incidence of anastomotic complications will be changed by using the modified technique.

Despite greater confidence in achieving a satisfactory pouch–anal anastomosis, a covering ileostomy seems to be advisable, not to prevent anastomotic dehiscence but to limit its effect should it develop.

It is too early to say from current studies that a stapled pouch–anal anastomosis is superior to the conventional trans-anal mucosectomy and manual pouch–anal anastomosis. A prospective controlled trial will be needed. There is no doubt that the technique we describe is quicker and easier to perform than the conventional procedure, and this is likely to encourage its more widespread use; however, internal anal sphincter function is impaired and anorectal mucosa is left. Both these defects may in the future limit its use.

A prospective study of prognostic factors has been carried out in a group of 186 patients with tethered rectal carcinomas. Of these, 97 were randomized to surgery alone and 89 to receive preoperative radiotherapy (20 Gy in four fractions). DNA ploidy was determined by flow cytometry. DNA aneuploidy was detected in 60 patients (62 per cent) in the surgery only group, but in only 33 patients (37 per cent) after radiotherapy ($P<0\cdot01$). *There was a significant reduction in local recurrence in irradiated patients* ($P<0\cdot0001$). *DNA diploid tumours were less likely to recur locally. This was more marked in the radiotherapy group* ($P=0\cdot01$) *than in the surgery only group* ($P=0\cdot06$). *After radiotherapy, only the surgeons' assessments of a 'curative' resection and DNA ploidy were independent predictors of local recurrence in multivariate regression analysis, whilst Dukes' classification was not. In conclusion, DNA ploidy may indicate response to radiotherapy and is an important predictor of subsequent local tumour progression.*

Keywords: Rectal cancer, radiotherapy, DNA ploidy, flow cytometry

There has been little change in the prognosis for patients with rectal cancer since the middle of this century. It may be possible to improve the results of surgery[1] but it is unlikely that advances in surgery alone will have a major impact on survival. Consequently, there is a need for effective adjuvant therapy for patients for whom surgery is not curative. Radiotherapy can cure small tumours in the lower rectum[2] and provides useful palliation for patients with symptomatic advanced disease[3]. There may also be a role for radiotherapy as an adjuvant to surgery administered either before or after operation[4–6]. As alternative forms of treatment are developed there is a need to identify factors which help to select those patients likely to benefit and which predict subsequent tumour progression. This study investigates tumour DNA ploidy, determined by flow cytometry[7], in patients with rectal carcinomas in a randomized trial of preoperative radiotherapy, and assesses its value as a predictor of response.

Patients and methods

Patients

The North West Rectal Cancer Trial is a prospective multicentre study designed to evaluate adjuvant preoperative radiotherapy in patients with locally advanced, tethered rectal carcinomas. Patients were recruited between 1982 and 1986; 141 were randomized to surgery only and 143 to adjuvant radiotherapy (20 Gy in four daily fractions using a 4 MeV linear accelerator) immediately before resection. Surgery was performed at the referral hospital and radiotherapy was administered at the regional radiotherapy centre (Christie Hospital). The operating surgeon reported a 'curative' resection if the carcinoma was resected and there was no macroscopic evidence of residual local disease or distant metastases. Dukes' classification was determined at the referring hospital but histological grade was reassessed by a single pathologist to exclude interobserver variation. Patients have been subject to regular review and carcinoembryonic antigen measurements. Local recurrence was diagnosed by clinical examination and computed tomography. Patients with elevated carcinoembryonic antigen levels also had a computed tomographic (CT) scan. Pathological material for flow cytometry was obtained for 97 patients in the surgery only group and 89 in the radiotherapy group, representing patients from the main referral centres. A total of 98 patients from other centres were excluded because of difficulty in obtaining archival pathological material for reassessment. Patients were randomized within hospitals, so those studied by flow cytometry are representative of the whole group.

Flow cytometry

Samples for flow cytometry were prepared using routinely processed histological specimens, fixed in formol–saline and paraffin-embedded[7,8]. Sections 50 μm thick were dewaxed in xylene, rehydrated through decreasing concentrations of ethanol and washed in distilled water. Nuclei were released by cytoplasmic digestion using 0·5 per cent pepsin in 0·9 per cent NaCl, pH 1·5. Samples were centrifuged and the nuclear pellets resuspended in 1 μg of 4′,6-diamidino-2-phenylindoldihydrochloride (DAPI) per ml of RPMI (Rosewell Park Memorial Institute) tissue culture medium. Suspensions were filtered through 35 μm nylon mesh and analysed on a Coulter EPICS V (Coulter Electronics Luton, UK) flow cytometer using ultraviolet (357 nm) excitation. From each sample 20 000 nuclei were analysed and DNA histograms were constructed. The full peak coefficient of variance of the diploid peak was calculated using the incorporated software. DNA aneuploidy was defined as the presence of at least two distinct G0/G1 peaks[9], provided the abnormal peak contained at least 10 per cent of the total number of nuclei analysed. The DNA index was determined by dividing the mode channel of the aneuploid peak by that of the diploid peak. The proportion of aneuploid nuclei was calculated as a percentage of the total number of nuclei analysed.

Statistics

Statistical comparison was made using the χ^2 test and Mann–Whitney *U* test. Survival information up to 30 months is available for 172 patients having DNA ploidy measurements. Survival curves were constructed using the life table method. For local recurrence free survival curves, patients dying without local recurrence were treated as censored observations at the time of death and cumulative proportions local recurrence free, calculated for those at risk. Univariate survival analysis was performed using the log rank test and the independent prognostic significance of variables was determined by Cox's multivariate regression analysis.

This study was supported by the North West Regional Health Authority and the Cancer Research Campaign. Members of the North West Cancer Group are listed in the Appendix to this paper.

Results

DNA ploidy

A mean of 2·4 blocks was analysed from each tumour. The mean(s.d.) coefficient of variance was 7·3(1·8) per cent. DNA aneuploidy was detected in 60 of 97 (62 per cent) tumours in the surgery only group but in only 33 of 89 (37 per cent) tumours after radiotherapy ($\chi^2=10{\cdot}42$, $P<0{\cdot}01$). The distribution of DNA aneuploid tumours according to the DNA index was similar in both groups, being clustered around the triploid and hypotetraploid levels. The proportion of nuclei in DNA aneuploid peaks was significantly higher in the surgery only group (mean 30·0 per cent, s.d. 13·5) compared with the radiotherapy group (mean 24·2 per cent, s.d. 10·9; Mann–Whitney *U* test, $P=0{\cdot}03$).

Survival

The survival rates for patients in the surgery only and radiotherapy groups were similar and most deaths were due to the progression of distant metastases outside the radiotherapy fields. However, there was a highly significant reduction in the number of local recurrences in the radiotherapy group (*Figure 1*). There was a survival advantage for patients with DNA diploid tumours in the surgery only group; 67 per cent of patients with DNA diploid tumours were surviving compared with 43 per cent of patients with DNA aneuploid tumours ($P=0{\cdot}04$). In the radiotherapy group there was a non-significant DNA diploid survival advantage ($P=0{\cdot}18$) The prognostic significance of other clinical and pathological variables in univariate analysis is shown in *Table 1*. Variables of independent prognostic significance by regression analysis in the surgery only group were: Dukes' classification ($P=0{\cdot}0006$), the surgeons' assessments of a 'curative' resection ($P=0{\cdot}003$) and histological grade ($P=0{\cdot}02$). In the radiotherapy group the only independent prognostic factors were 'curative' resection ($P=0{\cdot}0005$) and Dukes' classification ($P=0{\cdot}002$). DNA ploidy did not confer independent prognostic information for survival in either group.

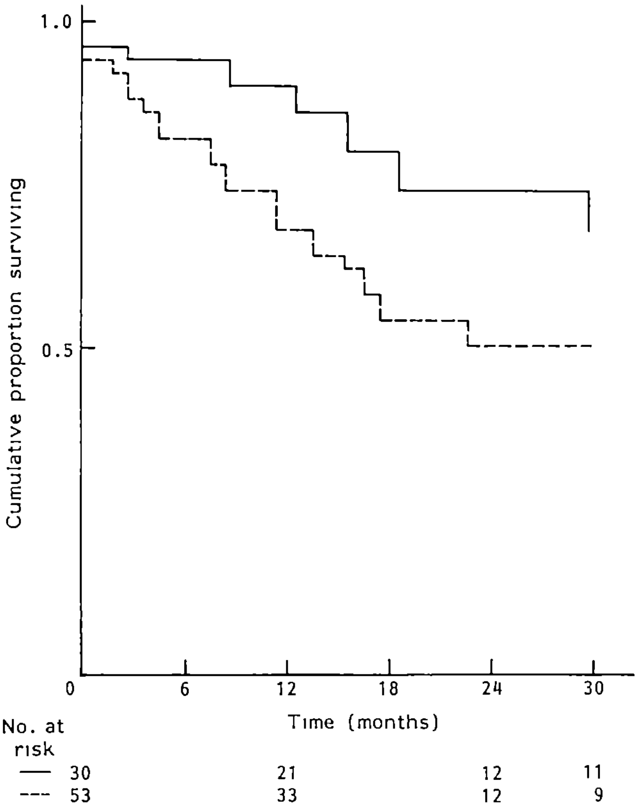

Figure 2 *Cumulative proportional survival in surgery only patients Local recurrence free. DNA diploid compared with DNA aneuploid, —— diploid, --- aneuploid,* $\chi^2=3{\cdot}67$, *1 d.f.*, $P=0{\cdot}06$

Local recurrence

There was a DNA diploid local recurrence free advantage for patients with DNA diploid tumours in the surgery only group Of those at risk, the cumulative proportions local recurrence free were 68 per cent of patients with DNA diploid tumours and 50 per cent with DNA aneuploid tumours ($P=0{\cdot}06$; *Figure 2*). DNA ploidy status after radiotherapy was a more powerful predictor of local recurrence, 90 per cent of at risk patients with DNA diploid tumours were free of local recurrence compared with 58 per cent of patients with DNA aneuploid tumours ($P=0{\cdot}01$; *Figure 3*). The relationship between other clinical and pathological features and local recurrence in univariate analysis is shown in *Table 2*. Independent predictors for local recurrence in the surgery only group were: Dukes' classification ($P=0{\cdot}00003$), DNA ploidy ($P=0{\cdot}002$), 'curative' resection ($P=0{\cdot}01$) and age ($P=0{\cdot}03$). After radiotherapy the only independent predictors of local recurrence were 'curative' resection ($P=0{\cdot}000008$) and DNA ploidy ($P=0{\cdot}003$).

DNA aneuploid subgroups

DNA aneuploid subgroups were defined according to DNA index; either 1·1–1·8 or 1·9–2·1 (DNA 'tetraploid') and

aneuploid peak size[10], but these did not confer any additional prognostic information.

Discussion

The measurement of cellular DNA content by flow cytometry is emerging as a potential aid in the pathological assessment of human tumours. In colorectal cancer most investigators report a survival advantage for patients with DNA diploid tumours[7], but, to date, this prognostic information has found little clinical application. In the present study, the incidence of DNA aneuploidy and the DNA diploid survival advantage for patients treated by surgery alone are in keeping with earlier studies of primary colorectal carcinomas[7]. After radiotherapy the detection of DNA aneuploidy decreased, reflecting local response to treatment with the eradication of DNA aneuploid cells in a proportion of tumours. Radiotherapy reduced local recurrence, although survival was unaffected as most deaths were due to the progression of distant metastases outside the radiation field. The local recurrence rates were high, reflecting the locally advanced nature of tumours at entry into the trial. They are comparable to those in patients with advanced carcinomas in other studies[11,12] and emphasize the need for effective surgery[1] and adjuvant therapy. The postirradiation DNA ploidy status ceased to be a significant predictor of survival because changes in DNA ploidy status were not matched by altered survival rates. Therefore, if DNA ploidy is used to predict survival the information should be obtained before radiotherapy.

The DNA ploidy status of a tumour after radiotherapy was an important predictor of local tumour progression. If DNA aneuploidy is detected after radiotherapy, viable tumour cells are still present and repopulation of residual tumour and local recurrence will occur. After radiotherapy the predictive power of DNA ploidy for local recurrence increased in contrast to conventional histology which decreased. Radiotherapy induces tumour necrosis which may cause difficulties in the histological assessment of the primary tumour and lymph nodes within the radiotherapy fields. This probably accounts for the downstaging of rectal cancers observed after radiotherapy[5].

The response to radiotherapy was not uniform suggesting that there are biological differences in radiosensitivity. The greatest response appeared to be in those DNA aneuploid tumours where the aneuploid population was eradicated. Dyson *et al.*[13] studied DNA ploidy in patients with carcinoma of the uterine cervix treated by radiotherapy and suggested that DNA aneuploid tumours were more radiosensitive than DNA diploid tumours. The reasons for differences in sensitivity are uncertain but may reflect different proliferative rates and stability. There are insufficient data at present to select rectal cancer patients for radiotherapy on the basis of DNA ploidy but those with DNA aneuploid tumours appear most likely to benefit.

In conclusion, DNA ploidy measurements are readily obtained using routinely processed pathological specimens and could be used to stratify patients in radiotherapy trials. DNA ploidy may indicate response to preoperative radiotherapy and is an important predictor of subsequent local tumour progression.

The diagnostic potential of endoluminal (endorectal and endovaginal) ultrasound to detect asymptomatic resectable local recurrence after rectal cancer surgery has been assessed in 120 patients: 17 recurrences (14 per cent) were detected. The method showed 97 per cent accuracy, 94 per cent sensitivity and 98 per cent specificity; the positive predictive value was 85 per cent and the negative predictive value was 99 per cent. A longer follow-up is, however, necessary to confirm these results. Of the 17 patients with local recurrence, six were asymptomatic and underwent reoperative surgery. Of the other 11 patients with symptomatic recurrence, only two underwent reoperative surgery.

Keywords: Rectal cancer, local recurrence, endoluminal ultrasound

Despite a better understanding of the natural history of large bowel cancer and the availability of stapling devices[1,2], the 5-year survival rate of patients operated on for rectal cancer remains approximately 50–60 per cent[3,4]. This is due in large measure to the frequent development of distant metastases[5] and local recurrence[6,7]. While distant metastases represent the expression of systemic disease, local recurrence may be due to a failure of surgery and is an outcome that is dismaying for any surgeon who believed that a radical clearance of tumour had been achieved.

Local recurrence usually occurs early (70–80 per cent of recurrences become manifest within 2 years of surgery[2,4,8]) and with a variable but high incidence (6–32 per cent)[1,3,4,6,9–12]. The incidence rises even higher (to 38 per cent) with longer postoperative follow-up and when autopsy studies are performed to detect clinically undetectable recurrence[13]. Local recurrence is particularly troublesome to the patient as it frequently causes an earlier and more painful death than metastases[14]. The most important factor associated with such recurrence now seems to be the local and, in particular, the lateral spread of the primary tumour[15,16].

Prevention is undoubtedly the best 'treatment' for local recurrence[17–19]. The poor results of reoperative surgery for symptomatic recurrence have led many to believe that the primary operation is the best opportunity available to the surgeon[14]. However, one must also be prepared to deal with recurrence when it develops, especially as local recurrence, even when it is the only site of redevelopment of the disease[14], is often the cause of death. Reoperative surgery offers the only method of obtaining good palliation and in some cases may even result in cure[14]. Such curative reoperative surgery depends mainly on the early detection of recurrence[4,14,20].

We have evaluated the diagnostic potential of endoluminal (endorectal and endovaginal) ultrasound in the postoperative follow-up of patients who have had surgery for rectal cancer, in an attempt to detect recurrence at an early stage, thus allowing potentially curative surgery

Patients and methods

We performed endoluminal ultrasonography in 120 patients (69 male, 51 female) operated on for rectal adenocarcinoma at from 3 to 14 cm from the anocutaneous line. Seven patients underwent local excision, 90 had an anterior resection and 23 had abdominoperineal excision of rectum. All patients were studied by a single observer (D M.) and the examination was performed on an outpatient basis with each examination lasting an average of 15 min.

The 1850 Bruel and Kjaer radial probe (Bruel and Kjaer, Naerum, Denmark) was used. Its diameter was 1 8 cm (in cases of stenosis a 0 5 cm diameter probe was preferred). The total length of the probe was about 24 cm. A 7 MHz transducer (focal length 2–5 cm) was generally employed, but if recurrence extended further a 4 MHz transducer with a longer focal length (3–7 cm) was used. If stenosis was present, the examination was performed with an antegrade view transducer of 5·5 MHz. The transducer was encased in a thin rubber balloon and filled with 50–60 ml degassed water, which distended the rectal wall and produced acoustic contact with it. The transducer rotated at a rate of 4–6 cycles per second with a 360° display of the rectal wall and surrounding tissues.

After following a low roughage diet for 2 days, the patient was given an enema to empty the rectum and was then examined, with full bladder, in a left lateral decubitus position. The probe was covered with acoustic coupling gel and inserted, after digital exploration, into the rectum through a rigid rectoscope 20 mm in diameter, which allowed a safe, high insertion. In this way the probe could be positioned as far as 20 cm beyond the anocutaneous line, the limit depending on the anatomical modifications caused by the operation. A scale on the probe indicated the distance from the anocutaneous line. The examination started from the point furthest from the anus. The rectal wall and, in particular, the perirectal spaces (ischiorectal and pelvirectal fossae and presacral space) were examined by slowly withdrawing the probe towards the anal canal. Comparison between ultrasound images obtained in preoperative staging of rectal tumours and those from operative specimens has demonstrated that neoplastic tissue usually appears as a hypoechoic, non-homogeneous mass with well defined margins[21,22] (*Figures 1* and *2*). The patient was first examined about 30 days after surgery to delineate the new anatomical conformation, and the images thus obtained were compared with those at subsequent examinations.

In our follow-up regimen, patients at high risk of recurrence (Astler and Coller's stages B2, C1 and C2)[23] were usually assessed for the first 2 years with the following techniques. Liver ultrasonography and estimation of the tumour markers carcinoembryonic antigen, gastrointestinal cancer antigen and tissue polypeptrol antigen were carried out every 3 months. Pancolonoscopy and chest radiography were performed every 6 months, and pelvic and abdominal computed tomography and bone scintigraphy were performed yearly These high risk patients were also evaluated by endoluminal-ultrasonography at 3-monthly intervals for the first 2 years and then at 6-monthly intervals for another 3 years. In the case of a radical local excision, ultrasound examination was performed every 2 months and a biopsy was taken every 4 months.

In female patients with anteriorly located recurrences, the endorectal examination was complemented with endovaginal ultrasonography (*Figures 3* and *4*). In female patients who had undergone an abdominoperineal excision of rectum, we performed the ultrasound examination *per vaginam* every 3 months, and combined it with pelvic computed tomography every 6 months. When an image raised a suspicion of recurrence, the examination was repeated after 40–50 days; if the mass was still present or increased in size, biopsy was performed. For a completely extramural mass, echo-guided biopsy was performed with a Tru-Cut® (Travenol Laboratories Incorporated, Deerfield, Illinois, USA) needle inserted transrectally, transvaginally or, more frequently, by a transperineal route. For echo-guided biopsy we often

used the sectorial 7 MHz probe which allowed better visualization of the needle. If the mass was intramural but not yet protruding into the rectal lumen, biopsy was performed endoscopically, even on an apparently healthy mucosa, at the site indicated by ultrasound (*Figure 5*).

Patients with recurrence were classified into three groups[24] as follows: group 1 included asymptomatic patients in whom recurrence was not demonstrated by any means other than by endoluminal ultrasonography; group 2 included symptomatic patients in whom local recurrence was confirmed by endoluminal ultrasonography but not by digital exploration and/or colonoscopy and/or pelvic computed tomography; group 3 comprised symptomatic patients in whom one or more of the above diagnostic methods, other than endoluminal ultrasonography, detected recurrences which were then confirmed by endoscopic or computed tomographically guided biopsy.

Results

Of 120 rectal cancer patients undergoing endoluminal ultrasound examination during the period from January 1986 to January 1988, recurrence was detected in 17 cases (14 per cent). All of these patients were examined on a minimum of two occasions after operation. No significant complications were related to the ultrasound examination.

The procedure showed 97 per cent accuracy, 94 per cent sensitivity and 98 per cent specificity. The negative predictive value was 99 per cent and the positive predictive value was 85 per cent. Although endoluminal ultrasonography was routinely repeated after 40–50 days in order to confirm an initial suspicion of recurrence, the positive predictive value of 85 per cent was still unsatisfactory, and biopsy for confirmation was always performed. We have had two apparent false positive ultrasound results, one of which was disproved by echo-guided biopsy and the other by second-look surgery. These patients, however, are still being followed closely and may yet prove to have local recurrence. We had one false negative result in a patient whose recurrence was confirmed by endoscopic biopsy; this patient had a stenosis which permitted the use of only the antegrade view 5·5 MHz transducer. Echo-guided biopsy was performed in nine patients (one transrectally, two transvaginally and six transperineally) and confirmed the presence of recurrence in eight. However, in three of these patients it was necessary to perform a second biopsy to obtain a positive result. Biopsy in the remaining patient proved to be negative.

Out of 17 recurrences detected by endoluminal ultrasonography, 12 were diagnosed by endorectal and five by endovaginal ultrasonography (*Table 1*). The six asymptomatic patients in group 1 had further surgery. Five of these recurrences which were detected by endorectal ultrasound were treated by abdominoperineal excision of rectum (four were 'curative' and one was palliative). The remaining patient, a woman already

treated with a Miles' operation, underwent 'curative' resection of a small recurrence detected by endovaginal ultrasound.

The operative specimens confirmed the presence, localization and size of the recurrences detected by endoluminal examination. In all six asymptomatic patients, recurrences were localized only in the pelvis (one intraparietal, two in the rectosacral space, one in the pelvirectal fossa, one between the rectum and the vagina, and one posterior to the vagina). All of these recurrences, which were treated by further surgery, were found to be less than 3 cm in diameter (range 8–28 mm).

All six patients in group 1 are still alive with a follow-up duration of between 4 and 15 months. In two patients, one of whom underwent 'curative' surgery, relapse was confirmed by computed tomography after 4 and 7 months; the other four patients are apparently still free of disease.

In group 2 there were four recurrences, two revealed by endorectal and two by endovaginal ultrasonography. Only one patient, already treated by anterior resection, underwent palliative abdominoperineal excision of rectum. This patient is still living, albeit with residual tumour, after 4 months. Of the remaining three group 2 patients, two underwent palliative radiotherapy and are both alive, with recurrence, at 12 and 14 months, and one received only supportive treatment and died 3 months later.

Of the seven patients in group 3, digital examination was positive in three cases, endoscopy in four and computed tomography in five. The only patient who underwent surgery was treated by palliative abdominoperineal excision and died after 7 months. Three patients with distant metastases had chemotherapy: two died after 5 and 7 months, and one is alive with recurrence at 13 months. The remaining three patients received only supportive treatment. Two died at 4 and 6 months after the diagnosis of recurrence and one is still alive, with recurrence, 1 year later.

Table 1 *Details of 17 patients with recurrence out of 120 patients studied by endoluminal ultrasonography after surgery for rectal cancer*

Endoluminal ultrasonography*	No. of patients	Treatment	Results	Follow-up (months)	Other positive procedures
Endorectal

Discussion

These findings confirm that the feasibility of reoperative surgery for local recurrence depends not only on the type of operation performed on the primary tumour (abdominoperineal excision does not easily lend itself to reoperation[14,25]) but also on the early detection of recurrence[20]. The possibility of reoperative surgery markedly increases when recurrence is diagnosed in asymptomatic patients, which highlights the importance of careful follow-up[9,26–28]. The proportion of potentially curative reoperative surgery for local recurrence increases from 2–14 to 40 per cent when patients are followed up closely with regular endoscopic assessment[4,8,9,20,27]. The worth of follow-up should not be based on the number of examinations performed each year, but on the actual effectiveness of the methods employed.

It is important to emphasize the difficulty of detecting local recurrence, not only after abdominoperineal excision but also after sphincter-saving resection. In the latter cases endoscopy plays a major part[29], but the frequently extramural growth of recurrences ('iceberg recurrences') does not always permit an early endoscopic diagnosis[4,30]. For this reason, computed tomography is as important after anterior resection as it is after abdominoperineal excision[31,32]. For the early detection of recurrence, frequent assessments are required[32], but the repeated use of computed tomography is undesirable because of radiation exposure and cost.

Endoluminal ultrasonography links much of the diagnostic potential of colonoscopy (endoluminal) and computed tomography (extramural). It is also a particularly favoured technique as it is simple to execute, it can be performed on an outpatient basis, it is well tolerated, it does not involve X-ray exposure, and it is cheap. In summary, endoluminal ultrasonography is ideal for repeated use in the monitoring of the operated patient.

All patients operated on for colorectal cancer can be examined if the probe can reach the level of the anastomosis. In the present study, however, only rectal cancer patients were included. While the routine use of staplers allows more frequent conservative surgery[2], this may require a greater employment of endorectal ultrasound for follow-up. A stapled anastomosis does not adversely affect the ultrasound image in that the visualization of its double hyperechoic row gives a reference point for identification of the anastomosis. In some patients, during surgery on the primary tumour, we positioned the omentum between the rectum and the sacrum to create a 'thickness' with the intent of facilitating the postoperative ultrasonic study of the rectosacral space (the area with the highest risk for development of recurrence). The usefulness of this surgical procedure has still to be confirmed.

When recurrence protrudes into the rectal lumen, colonoscopy is a more useful technique than ultrasonography. However, in the early stages, recurrence is often represented by a thickening of the rectal wall or, more frequently, by an extraparietal mass. The ultrasound image of such lesions usually consists of a perirectal, round, hypoechoic and non-homogeneous mass, which is completely extramural in the early stages with later infiltration of the rectal wall. Differentiation between postoperative fibrosis and recurrence is not always easy; subsequent morphological and volumetric changes are of the utmost importance.

Whenever a recurrence is suspected, it should always be proved with biopsy, but this is performed only after two or more abnormal examinations to avoid excessive invasive testing. Of the 120 rectal cancer patients undergoing postoperative endoluminal ultrasonography, we observed only two false positives and one false negative. These results should be critically evaluated in view of the fact that ultrasonic diagnosis cannot be easily contradicted by other diagnostic procedures or by second-look surgery. A longer follow-up may temper present optimism.

Although endoluminal ultrasonography may allow early diagnosis and potentially curative revisional surgery, it may also have a place when recurrence has already been diagnosed by other methods. The ultrasound examination may confirm and more accurately define the extent of neoplastic infiltration. When radiotherapy is required, ultrasound images facilitate a more precise focusing and permit assessment of the efficacy of the treatment by repeated measurement of the size of the lesion.

In conclusion, even though they must be confirmed by larger studies and longer follow-up, our results show that endoluminal ultrasonography should be routinely performed in the postoperative follow-up of rectal cancer patients. The main objective is the early detection of recurrence suitable for 'curative' surgery.

Between January 1984 and May 1988, 25 patients with fourth degree haemorrhoids were treated in the acute phase by lateral internal sphincterotomy under narcosis. Pain relief was immediate. The median hospital stay was 3 days. The median follow-up period was 26 months. For 20 patients a single lateral internal sphincterotomy alone was adequate treatment. If further therapy was required, simple band ligation was enough. There was one recurrence, which was treated with a further lateral internal sphincterotomy. In the long term, 18 patients had no complaints and seven had only minor complaints. Twenty-three patients were very satisfied and two were moderately satisfied. Nobody was dissatisfied. Lateral internal sphincterotomy is an attractive alternative in the treatment of fourth degree haemorrhoids, its major benefits being simplicity, efficiency and low morbidity.

Keywords: Fourth degree haemorrhoids, lateral internal sphincterotomy

In fourth degree haemorrhoids, according to the classification of Thomson and Leicester[1] (also called 'acute haemorrhoidal disease' or 'attack of the piles'), prolapsed haemorrhoids become trapped in a vicious circle of pain, increased sphincter tone and venous engorgement. Usually the event is incited by straining at stool. It leads to oedema, thrombosis and eventually necrosis of the pile mass (*Figure 1*). The predominant clinical symptom, which is often very dramatic, is pain, and this causes the patient to consult the physician for relief.

Left unattended, the natural course of events in the majority of cases is one of spontaneous resolution over a period of weeks, leading either to symptomatic improvement of the pre-existing haemorrhoids or, rarely, to large fibroid masses at the anal orifice. Rare complications are necrosis, infection and even portal pyaemia[2].

The usual choice of treatment is between conservative management and emergency haemorrhoidectomy, the latter being the standard against which alternatives must be compared[3–9].

This study investigated the role of lateral internal sphincterotomy as an alternative treatment, which avoids the early morbidity and late sequelae of classical haemorrhoidectomy.

Patients and methods

Between January 1984 and May 1988 25 patients with fourth degree haemorrhoids were seen at the St. Elisabeth Hospital. These comprised 16 men and nine women of median age 44 years (range 13–81 years). All were treated by lateral internal sphincterotomy.

Lateral internal sphincterotomy was performed under general anaesthesia, with the patient in the jack-knife position. After preliminary infiltration with a diluted adrenaline solution, the internal sphincter was exposed laterally (*Figure 2*) and divided with scissors up to the level of the dentate line (open lateral subcutaneous sphincterotomy[1]). For reasons of haemostasis, the right lateral approach, between the anterior and posterior piles, was usually appropriate. Subsequently prolapse was, whenever possible, reduced.

Results

Postoperative morbidity

There was a consistent, immediate and dramatic relief of pain. Oedema, thrombosis and prolapse remained for a varying length of time but gradually subsided in the few days after surgery. The median hospital stay was 3 days (range 0–13 days).

Additional therapy

For 20 of the 25 patients a single lateral internal sphincterotomy was adequate treatment. For those five patients who needed further therapy because of residual second or third degree haemorrhoids, simple band ligation was done within a few months of lateral internal sphincterotomy. Haemorrhoidectomy was never necessary.

Recurrence

In one case, fourth degree haemorrhoids reoccurred after 26 months. A second lateral internal sphincterotomy was performed and no other treatment was required.

Long-term results

After a median follow-up period of 26 months (range 1–56 months), 18 patients had no complaints about their condition and seven patients had only minor complaints (*Table 1*). Most had to be asked specifically about incontinence of which none complained spontaneously, presumably because of its intermittent and mild nature. At inspection 19 patients had no haemorrhoids, one had first degree haemorrhoids, and five had second degree haemorrhoids. Twenty-three patients were very satisfied, two were moderately satisfied and none was dissatisfied.

Discussion

The treatment of haemorrhoids has evolved because of new insight into the anatomy and pathophysiology of the condition. According to Thomson[10] and Haas *et al.*[11], haemorrhoids are vascular cushions supported by connective tissue and secured to the internal sphincter and conjoined longitudinal coat by anchoring connective tissue. This connective tissue deteriorates with ageing and as a result the haemorrhoids not only bulge but also descend into the anal canal. Band ligation and sclerotherapy aim at reducing the vascular cushions to their normal size and resecuring them to the internal sphincter.

The relationship between the internal sphincter and haemorrhoids has attracted the attention of many authors. Allgower[12] stated that venous outflow from the haemorrhoidal plexus partially runs through the internal sphincter and that sphincteric hyperfunction leads to a vicious circle of venous engorgement, pain at defaecation and a further rise in sphincter tone. He reported the results of 111 sphincterotomies for from first to fourth degree haemorrhoids. His success rate was 95 per cent, with six recurrences which were treated by lateral internal sphincterotomy. Hancock[13] and Hancock and Smith[14] noted increased internal sphincter tone in patients with haemorrhoids. Treatment using Lord's procedure gave satisfactory symptomatic improvement and a reduction in resting anal pressure.

Arabi *et al.*[15] found significantly higher anal pressures in patients whose haemorrhoids caused pain and bleeding. These were usually men aged less than 46 years. Read *et al.*[16] noted that the increased internal sphincter tone in patients with haemorrhoids disappeared after haemorrhoidectomy, suggesting it to be the effect rather than the cause of the haemorrhoids. Schouten and van Vroonhoven[17], using lateral internal sphincterotomy in the treatment of patients with from first to third degree haemorrhoids and high anal pressure at manometry, were especially successful in managing patients in whom pain and bleeding were the main presenting symptoms. Gibbons *et al.*[18] found increased maximum resting pressures in patients of both sexes with second or third degree haemorrhoids, although this reached statistical significance only in men.

Lateral internal sphincterotomy is well known to be a simple, effective way of reducing internal sphincter tone without impairing its function[1,17]. Because of this we have adopted this technique along with band ligation in our treatment for from first to third degree haemorrhoids (*Table 2*), and the present study has examined its use in fourth degree haemorrhoids.

Our reasons for not treating fourth degree haemorrhoids classically with emergency radical haemorrhoidectomy are twofold. Firstly, like others, we find haemorrhoidectomy more difficult in the acute condition, and it is certainly not an operation for the inexperienced. There is especially the risk of causing inadequate skin bridges between the haemorrhoidectomy wounds, which predisposes to anal stenosis. To avoid this complication Mazier[9] advocated maximal three-quadrant excisions, Hansen and Jorgensen[6] usually excised not more than two piles, and Heald and Gudgeon[7] advised limited haemorrhoidectomy with excision of only the largest prolapsed haemorrhoid. Obviously it is not necessary to excise all prolapsed tissue to achieve good results: debulking is sufficient. Secondly, emergency radical haemorrhoidectomy is associated with postoperative pain and although this may be less than the preoperative pain, or the pain associated with conservative management, it may still be substantial[8]. In this respect a definite beneficial effect from the addition of an internal sphincterotomy to haemorrhoidectomy has been noted in patients aged under 40 years[8].

In an attempt to avoid these drawbacks of emergency haemorrhoidectomy, we decided to extend our rationale to the treatment of fourth degree haemorrhoids. Lateral internal sphincterotomy performed in the acute condition should interrupt the vicious circle, thereby reducing the fourth degree haemorrhoids to third or second degree haemorrhoids. In due course these could be treated with simple band ligation.

Our results show that treating fourth degree haemorrhoids by lateral internal sphincterotomy leads to immediate relief of pain (confirmed by all patients), a short hospital stay and few long-term complaints. It is usually adequate as a single treatment but if further treatment is eventually required, this may simply consist of band ligation.

In conclusion, we are convinced that lateral internal sphincterotomy is an attractive alternative to emergency haemorrhoidectomy in the management of fourth degree haemorrhoids. Its major benefits are simplicity, efficiency and low morbidity.

Table 2 *Treatment policy with regard to degree of haemorrhoids*

Degree	Patients aged <50 years	Patients aged >50 years
First	Lateral internal sphincterotomy	Band ligation
Second	Lateral internal sphincterotomy	Band ligation
Third	Band ligation	Band ligation

Prognosis after surgery for colonic Crohn's disease

H. A. Andrews, P. Lewis and R. N. Allan

Gastroenterology Unit, General Hospital, Steelhouse Lane, Birmingham B4 6NH, UK

Correspondence to: Dr R. N. Allan

The long-term prognosis including operation rates, the incidences of recurrent disease, morbidity and mortality and current status has been analysed in a group of 360 patients with Crohn's colitis grouped according to the primary site of macroscopic disease at diagnosis. The group has been followed from diagnosis for a mean period of 14·9 years. The overall operation rate was 76 per cent. Prolonged spontaneous or drug induced remission occurred at all sites: right-sided disease (11 per cent), extensive colonic disease (21 per cent) and left-sided disease (38 per cent). The cumulative reoperation rates at 5 and 10 years after right hemicolectomy were 26 and 46 per cent, after colectomy and ileorectal anastomosis 46 and 60 per cent, and after panproctocolectomy 10 and 21 per cent, respectively. There was a twofold excess mortality rate from related Crohn's disease deaths during the period of review, but the mortality rate has fallen with time. There have only been 11 related deaths in the last decade, of which eight were probably unavoidable. The current status of most patients is good, although treatment has included a permanent stoma in less than half (41 per cent) the patients still under review. Currently all but 14 patients are well and symptom-free and only 16 are receiving specific medical treatment. Until the aetiology of Crohn's colitis is understood, if medical treatment has failed to resolve symptoms, appropriate surgical treatment in experienced hands is an effective way of restoring patients with chronic persistent symptoms to good health.

Keywords: Crohn's disease, colon surgery, large intestine

There have been few studies of the long-term prognosis of Crohn's disease involving the colon[1–4]. In this study, because there are many variables which influence the interval from diagnosis to initial resection, we have determined the long-term prognosis in all patients but particularly those who have undergone surgical treatment for Crohn's disease involving the colon.

Patients and methods

Among a consecutive series of 779 patients with Crohn's disease under review at the General Hospital, Birmingham, between 1944 and 1986, 360 (46 per cent) at diagnosis had evidence of Crohn's disease involving the large intestine (164 men, 196 women). The mean age at onset of symptoms was 37·2 years (range 3–78 years) with a mean interval from onset to diagnosis of 2·4 years (range 0–20 years). The mean duration of follow-up since diagnosis is 14 9 years.

Diagnosis

The diagnosis of Crohn's disease was confirmed by macroscopic and histological examination of the resected specimens in all 272 patients undergoing resection. Of the 88 patients treated conservatively, 74 had the clinical and radiological features of Crohn's disease (including 30 with granulomas on histological examination of rectal biopsy), 13 patients were diagnosed on histological examination of the rectal biopsy and one was diagnosed on the macroscopic appearance at laparotomy. The first radiological endoscopic or histological evidence consistent with Crohn's disease was used as the date of diagnosis.

Principles of management

The patients have been reviewed at least annually including clinical, biochemical and haematological assessment. Radiological examinations were performed in symptomatic patients and barium enema examination was particularly useful in identifying recurrent disease at anastomotic sites.

Disease activity

Disease activity was measured by changes in body weight. Serum orosomucoids were included from 1958 onwards. Serum albumin, haemoglobin and erythrocyte sedimentation rate were used throughout the study. Elevated serum orosomucoids and fall in serum albumin are of particular value in assessing colonic Crohn's disease activity.

Site of disease

The primary site of disease at diagnosis was right-sided (85 patients), left-sided or segmental (130 patients), or extensive (145 patients) colonic disease

The site of disease related to age at diagnosis is shown in *Figure 1*. Most patients over 60 years of age presented with left-sided colitis

Results

The results have been analysed in groups based on the primary site of disease at diagnosis.

Right-sided colonic involvement

All but ten of the 85 patients with right-sided disease also had macroscopic involvement of the adjacent distal ileum. Only nine patients (three men, six women) (11 per cent) have not required surgical treatment during the period of review and these patients have been followed for a mean of 13·5 years (range 4–32 years). All nine are currently alive and well, although three have developed extensive colitis during follow-up.

The most common indication for surgery in this group was obstructive symptoms. Other indications included abdominal abscess or fistula formation, general malaise, weight loss and diarrhoea. The mean interval between onset and surgery was 4 years (range 0–41 years). The cumulative operative rate with time from diagnosis among the patients undergoing resection is

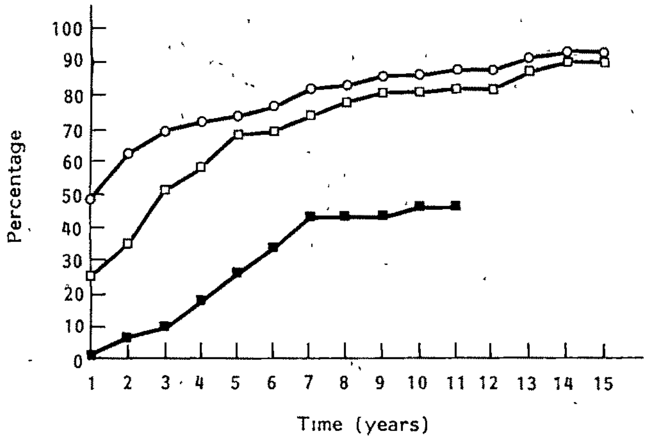

Figure 2 *Right-sided colonic disease. Cumulative operative rate from onset of symptoms* (□), *from diagnosis* (○), *and reoperative rate for recurrent disease after right hemicolectomy* (■)

shown in *Figure 2*. The cumulative operative rate was 35 per cent at 2 years, 68 per cent at 5 years and 81 per cent at 10 years from onset, and 62, 74 and 86 per cent respectively from diagnosis. The most common initial resection was right hemicolectomy (48), followed by colectomy and ileorectal anastomosis (12), bypass (five), panproctocolectomy (four) and others (seven). The surgical outcome in this group of patients is summarized in *Figure 3*. The cumulative reoperation rate for recurrent disease after right hemicolectomy is shown in *Figure 2*. The cumulative reoperation rate after right hemicolectomy at 2, 5 and 10 years was 7, 26 and 46 per cent respectively.

Left-sided disease

Of the 130 patients (60 men, 70 women) who presented with disease involving the sigmoid colon and/or rectum, 14 also had distal ileal involvement. Forty-nine patients (24 aged <40 years at diagnosis and 25 >40 years) had been treated without surgical treatment despite a mean follow-up of 8·2 years (range 0·1–42 years) from diagnosis. Of the 130 patients with left-sided disease, 81 (62 per cent) underwent resection after a mean interval of 6 years (range 0–25·2 years) from diagnosis. The main indications for surgery were persistent diarrhoea with general malaise, abscess or fistula formation, and troublesome perianal disease. In a few patients the initial resection was either of the distal ileum or right colon, where obstructive symptoms at this site were the major problem The cumulative operation rate from onset of symptoms to first operation and from diagnosis is shown in *Figure 4*. The operative rates from onset to first resection were 18 per cent at 2 years, 34 per cent at 5 years and 55 per cent at 10 years, and from diagnosis 36 per cent at 2 years, 53 per cent at 5 years and 67 per cent at 10 years.

The most common forms of surgical treatment were extensive resection involving either colectomy and ileorectal anastomosis, panproctocolectomy, colectomy and end ileostomy or segmental colectomy. The surgical treatment and outcome is summarized in *Figure 5*. Nearly half of the patients undergoing

operation (36 of 81) had either colectomy alone ($n=10$), colectomy and ileorectal anastomosis or panproctocolectomy. Among these patients treated by either ileostomy alone or colectomy and end ileostomy, the majority eventually needed either excision of the colon or rectum. Further colonic resection was uncommon in those treated by segmental colectomy or resection of the distal ileum or right hemicolectomy, as appropriate.

Crohn's proctitis

Of the 130 patients with left-sided colitis, 44 had macroscopic disease confined to the rectum (23 aged <30 years and 18 >50 years). Most have been diagnosed since 1970 (31 of 44, 70 per cent). Crohn's proctitis may occur at any age but Crohn's disease diagnosed in the older patient is nearly always confined to the rectum or left colon. Because most of the older patients can be treated conservatively, the cumulative operative intervention rate is lower than in other groups (22, 29 and 33 per cent at 2, 5 and 8 years from diagnosis respectively; *Figure 6*).

Extensive colonic disease

Of the 145 patients (69 men, 76 women) who had extensive colonic involvement at diagnosis, 101 had distal ileal involvement. Thirty patients (18 women, 12 men) have run a relatively benign course without surgery despite a follow-up period from diagnosis of 10 years (range 0·6–28·25 years). One hundred and fifteen patients (79 per cent) with extensive colonic disease underwent surgical treatment. The cumulative operative rates from diagnosis to first resection are shown in *Figure 7*. The cumulative operative rates from onset were 20 per cent at 2 years, 41 per cent at 5 years and 63 per cent at 10 years, and from diagnosis were 35 per cent at 2 years, 56 per cent at 5 years and 74 per cent at 10 years. Eighty-seven of the 115 patients had an initial extensive colonic resection (colectomy and end ileostomy, colectomy and ileorectal anastomosis or panproctocolectomy) and a further 18 patients (105 of 115 patients in total) had extensive colonic resection during the period of follow-up. Of the ten patients initially undergoing ileostomy alone, seven were subsequently treated by colectomy. Seven of the 12 patients undergoing right hemicolectomy or terminal ileal resection eventually required colectomy (*Figures 8–10*).

Colectomy and ileorectal anastomosis for Crohn's colitis

The outcome after colectomy and ileorectal anastomosis for Crohn's colitis is summarized in *Figure 9*. Of the 80 patients, 68 underwent colectomy and ileorectal anastomosis as a primary resection and 12 for resection of recurrent disease. Nearly half the patients (35 of 80) have not undergone further resections despite a mean follow-up since colectomy and ileorectal anastomosis of 6·8 years (range 0·1–20·8 years). The most common indication for reoperation was recurrent disease proximal to the ileorectal anastomosis, followed by reactivation of disease in the rectum leading to proctectomy. Reoperation rates for recurrent disease after colectomy and ileorectal anastomosis was completed are shown in *Figure 11*. Cumulative reoperation rate at 2, 5 and 10 years was 27, 46 and 60 per cent respectively

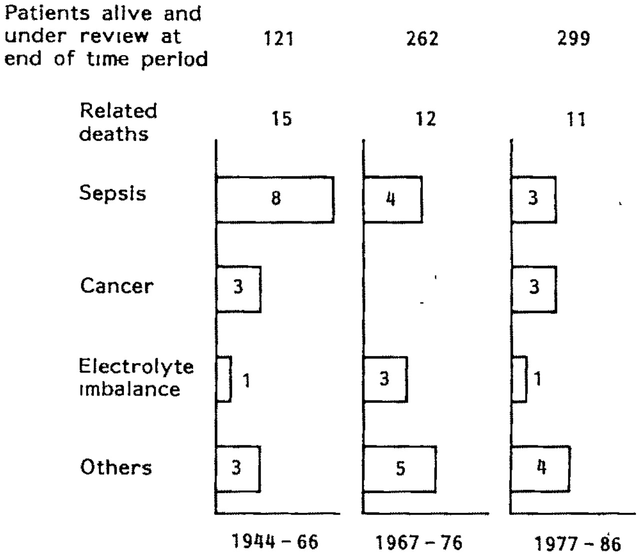

Figure 12 *Related deaths from Crohn's colitis*

colectomy of 8·2 years (range 0·2–30·1 years), 83 have not required further surgical treatment. The most common indication for reoperation is resection of recurrent disease in the distal ileum immediately proximal to the ileostomy. The cumulative reoperation rates after panproctocolectomy are shown in *Figure 11* and are 1, 10 and 21 per cent at 2, 5 and 10 years respectively.

Operative rates: primary and secondary referrals

The cumulative operative rate for patients referred from other hospitals is higher than among those patients in whom the diagnosis was made in this unit (64 *versus* 53 per cent at 5 years and 82 *versus* 62 per cent at 10 years).

Mortality

Of the 360 patients, 61 have died: 23 of unrelated causes. The 38 disease-related deaths are summarized in *Figure 12*. Despite the increasing number of patients under review there have only been 11 related deaths in the decade 1977–86, of which eight were probably unavoidable (*Figure 12*). The three potentially avoidable deaths were due to sepsis (two) and pulmonary embolus (one). Of the unavoidable deaths, three occurred from colorectal cancer complicating long standing colitis, one elderly woman presented with overwhelming sepsis, one 87-year-old patient presented with electrolyte imbalance and a decision was made not to undertake active treatment. One patient refused medical treatment and took corticosteroids at her own discretion, and one patient with chronic psychiatric problems was confined to bed and died of pulmonary embolus. The one remaining patient developed Takayasu's disease.

Current status

Of the 299 living patients, 285 are currently well (*Table 1*).

Right-sided disease. Of 85 patients with right-sided disease, 70 are alive. All nine patients treated conservatively are fit and well after a mean follow-up of 13·5 years, although three are known to have extensive colitis. Of 76 surgically treated patients, 58 are well, although 20 are known to have recurrent disease. Three are unwell and receiving corticosteroids (one has diffuse small bowel disease and two have total colitis). The duration of follow-up in the surgically treated group is 17 years (range 0·1–38·4 years).

Table 1 *Current status of 299 living patients*

Colonic disease	Management	Well	Well + corticosteroids	Unwell + corticosteroids
Right-sided	Conservative	9		
	Surgical	58		3
Left-sided	Conservative	42		1
	Surgical	65		4
Extensive	Conservative	24	1	
	Surgical	85	1	6
Total		283	2	14

Left-sided disease. Of 130 patients with left-sided disease, 112 are alive. Duration of follow-up was 8·2 years (range 0·1–42·7 years). Of the 49 treated conservatively, 43 are alive and all but one are well. Of the surgically treated group, duration of follow-up was 13·5 years (range 0·1–42·9 years); 69 of 81 are alive and all but four (who are taking corticosteroids) are well.

Extensive disease. Of 145 patients with total colitis, 117 are alive. Duration of follow-up was 10 years (range 0·6–28·2 years). All 25 survivors of the 30 patients treated conservatively are well and only one is taking steroids. Seven have total colitis of more than 10 years duration. Of the 115 surgically treated patients, 92 are alive and 86 are well (one on corticosteroids). Six are unwell and all are taking corticosteroids (*Table 1*). Duration of follow-up was 15·7 years (range 0·1–42·7 years).

Stoma patients. Of the total of 360 patients, 172 have had a stoma at some time (33 of 85 with right-sided, 50 of 130 with left-sided and 89 of 145 with extensive colonic disease). Of the 299 patients still alive, 122 have a stoma (14 with right-sided, 44 with left-sided and 64 with extensive colonic disease).

Discussion

This study of 360 patients under long-term review is biased towards the severely ill patient and contrasts with the epidemiological studies of Hellers[2] and Binder *et al.*[3]. It is, however, more representative of Crohn's colitis as seen in a hospital setting. The analysis has been mainly confined to the outcome after surgical treatment because the proportion of patients treated surgically will vary according to the nature and severity of symptoms among the patients studied.

Prolonged spontaneous or drug-induced remission occurred in all groups. The proportion among patients with right-sided disease was 11 per cent, extensive colonic disease 21 per cent and left-sided disease 38 per cent. These patients were not subject to prolonged or intensive therapy but probably represent a more benign end of the disease spectrum. Of the surgically treated patients most had either persistent symptoms amenable to surgical treatment (fibrous stricture, local abscess formation or enterocutaneous fistula) or symptoms which were not relieved by or had recurred following medical treatment, particularly general malaise, diarrhoea and weight loss.

In this series, after a mean interval from diagnosis of nearly 15 years, 76 per cent had undergone surgical treatment. Comparable figures of 39 per cent at 10 years were reported in a primary series from St. Mark's Hospital, London, UK of patients with Crohn's colitis seen between 1969 and 1973[4], and 55 per cent treated surgically after 10 years from diagnosis in an epidemiological study of Crohn's disease from Copenhagen[3].

Right-sided colonic disease

Symptoms in patients with right-sided colonic disease usually arise from the associated distal ileal involvement and the pattern of surgical intervention and reoperation rates are similar to those found in distal ileal disease[5]. The reoperation rates for recurrent disease following right hemicolectomy for right-sided colonic disease are 26 per cent at 5 years and 46 per cent at 10 years but, despite these relatively high reoperation rates, surgery is an effective way of restoring patients to good health – particularly those with short fibrous stricture.

Recurrent disease nearly always occurs at or around the anastomosis, resulting in clear-cut symptoms which, if they persist, can readily be resolved by further local resection. The outcome is unsatisfactory in a few patients where the disease, apparently confined to the right colon, initially recurs either diffusely in the small bowel or extensively in the colon, eventually requiring treatment by either colectomy and ileorectal anastomosis or panproctocolectomy (*Figure 3*). Bypass has only been undertaken in a few cases, its benefit is usually shortlived and most patients subsequently undergo resection.

Left-sided colonic disease

Although surgical treatment is not needed as commonly as in patients with extensive colitis, those patients who do warrant surgical intervention usually require either colectomy and ileorectal anastomosis or panproctocolectomy. Of patients treated initially by segmental resection most have subsequently required further surgery (*Figure 5*).

Crohn's proctitis

Patients with Crohn's disease confined to the rectum run a more benign course, predominantly because the older patient can usually be treated conservatively[6] and consequently surgical intervention rates are lower than at other sites (*Figure 6*).

Extensive colitis

Patients with extensive colitis at diagnosis can usually only be restored to good health by major surgical treatment. Ileostomy alone or segmental resection only temporarily improves symptoms (*Figure 8*).

When the rectum is spared or minimally involved, colectomy and ileorectal anastomosis is appropriate and nearly half the patients thus treated have not required further surgery despite a mean follow-up of 6 years. Nearly half of those requiring further surgical treatment had recurrent disease in the distal ileum which, after resection, enabled intestinal continuity to be restored.

Panproctocolectomy is particularly effective in restoring chronically ill patients to good health[7]; the risk of recurrent disease is small and is usually confined to the distal ileum immediately proximal to the stoma which is readily amenable to local resection if symptoms persist (*Figure 11*).

Acceptance of a permanent stoma is an integral part of management. Nearly half the patients (48 per cent) have required a stoma at some time during their management and, of the 299 patients still alive, 41 per cent have a permanent stoma. Most people with extensive Crohn's colitis will have persistent symptoms and prolonged ill health, and few are restored to good health without surgical intervention.

Mortality

A statistical study from this unit has demonstrated that deaths from Crohn's disease are twice as common as in the general population matched for age, sex and years at risk[8]. However, this overview conceals recent improvements. There have only been 11 related deaths in this series during the last decade, only three of which might have been classified as avoidable. This change in the pattern of mortality with time helps to explain the lower mortality observed in the recent series of Crohn's disease reported from Copenhagen[3].

Current status

Despite the high morbidity, the long-term prognosis is good as most patients are working full-time, undertaking housework or enjoying retirement. Currently only 14 have major symptoms and 16 are receiving specific medical treatment. Until the aetiology of Crohn's disease is identified, surgical treatment has an important and effective part to play in the overall management of patients with Crohn's disease.

Professor N. S. Williams

A new operation is described in which a neorectum and neoanal sphincter mechanism have been constructed to restore gastrointestinal continuity and continence in a patient who had previously undergone proctocolectomy and a permanent ileostomy. The neorectum was constructed by forming a triplicated pouch from the distal ileum. The neoanal sphincter was fashioned from a transposed gracilis muscle and was activated electrically by an implanted stimulator. A period of chronic low frequency stimulation altered the muscle characteristics and enabled the neosphincter to contract continually without fatigue. Complete continence was achieved by the neosphincter gripping a Silastic® plug inserted within the efferent spout of the pouch. The patient was able to void completely when the stimulator was switched off and the plug removed.

Keywords: Neorectum, electrically stimulated neoanal sphincter, protocolectomy

The surgical treatment for ulcerative colitis and familial adenomatous polyposis has been considerably improved in recent years by the introduction of mucosal proctectomy and pelvic pouch formation by Parks and Nicholls in 1978[1]. In this operation, all the diseased mucosa is removed by colectomy and rectal mucosectomy. Gastrointestinal continuity is restored by the creation of a pelvic ileal pouch which is sutured to the anal canal. Technical improvements have enabled most patients to have a reasonable bowel function, and the elimination of the ileostomy has enhanced the quality of their lives[2].

Despite this advance, there are patients with both ulcerative colitis and familial adenomatous polyposis in whom the operation fails or is contraindicated, and who by necessity must be left with a permanent ileostomy. In addition, there remain a considerable number of relatively young patients who have undergone proctocolectomy and ileostomy before the introduction of the pelvic pouch procedure. Whilst many of these patients remain satisfied with their ileostomy, a substantial proportion do not.

The dissatisfaction of one of our ileostomy patients led us to devise a new procedure, the purpose of which was to restore gastrointestinal continuity and continence by the construction of both a neorectum and a neoanal sphincter. The neorectum consisted of a pelvic ileal pouch and the neoanal sphincter was constructed from a transposed gracilis muscle[3], which was continually stimulated electrically by an implanted stimulator.

Patient and methods

A 29-year-old man first presented to The London Hosptal in 1986 requesting reversal of his ileostomy. His mother died of carcinoma of the colon at the age of 27 years and he was diagnosed as having familial adenomatous polyposis after a screening colonoscopy and, at the age of 18 years, underwent colectomy and ileorectal anastomosis. After this procedure his bowel function was acceptable but he developed numerous polyps in the rectal stump, many of which showed dysplastic change. It was not possible to control these with diathermy fulguration and in 1983 he underwent rectal excision and a Brooke end ileostomy. After this procedure, he never came to terms with his ileostomy and requested numerous opinions seeking reversal of the ileostomy.

Clinical examination revealed a fit young man with a healthy end ileostomy. The perineal wound was well healed and there was no sinus. Attempted voluntary contraction of the perineal region showed normal gluteal contraction but suggested the absence of the external anal sphincter and puborectalis muscles. The latter was confirmed by electromyographic examination. A small bowel meal showed no evidence of polyps. The new procedure together with the risks were fully explained to the patient and in April 1988 he underwent the first stage of the operation.

Operative technique

Stage 1. A laparotomy was performed with the patient in the modified Lloyd-Davies position and the ileostomy was mobilized from the abdominal wall. The small bowel was fully mobilized up to the root of the mesentery where the superior mesenteric vessels exit from above the third part of the duodenum. After ensuring that the distal 40–50 cm of ileum would reach the perineum, a triplicated ileal pouch (15 cm limbs) with a 1-cm efferent spout was manually constructed in two layers[1]. The pelvic dissection was then commenced and the ureters were identified, mobilized and preserved. The posterior wall of the bladder was identified and both this and the prostrate were mobilized and retracted anteriorly. The levatores ani were identified and cleared of debris and scar tissue. The junction of the two muscles was identified in the midline and a track was then created downwards between the muscles towards the perineal skin.

Via a perineal approach, a disc of skin and underlying fibrous tissue measuring about 2 cm in diameter was removed from the central part of the perineal scar. The dissection continued upwards to meet the tunnel previously created in the abdomen. This track was enlarged by manual stretching.

The ileal pouch was drawn down through the pelvic tunnel taking great care to ensure its correct orientation. The efferent spout was sutured circumferentially to the perineal skin using interrupted 3/0 Vicryl® sutures (Ethicon Ltd, Edinburgh, UK) (*Figure 1*). A covering loop ileostomy was then constructed about 20 cm proximal to the pouch. The postoperative course was uneventful and 4 weeks after the first procedure the second stage was performed.

Stage 2. With the patient in the modified Lloyd-Davies position a longitudinal incision was made in the left thigh. The left gracilis muscle was identified and mobilized down to its insertion into the tibial tuberosity. The tendon was divided and the proximal part of the muscle was fully mobilized[3] during which the neurovascular bundle was identified, using a nerve stimulator, where it entered the lateral border of the muscle in its proximal one-third. The principal nerve to the muscle was traced on to the lateral surface of the muscle. An electrode plate (Medtronic Resume, Medtronic Inc., Minneapolis, USA) containing four platinum–iridium electrodes was positioned over the main trunk of the nerve and its branches (*Figure 2*). The position of the electrodes was adjusted until a point was found where the voltage threshold for the contraction of the whole of the muscle was at its lowest (c. 2·0 V, 0·2 ms pulse at 1 pulse/second). When this position was located the electrode plate was sutured into position with interrupted fine silk sutures, taking care

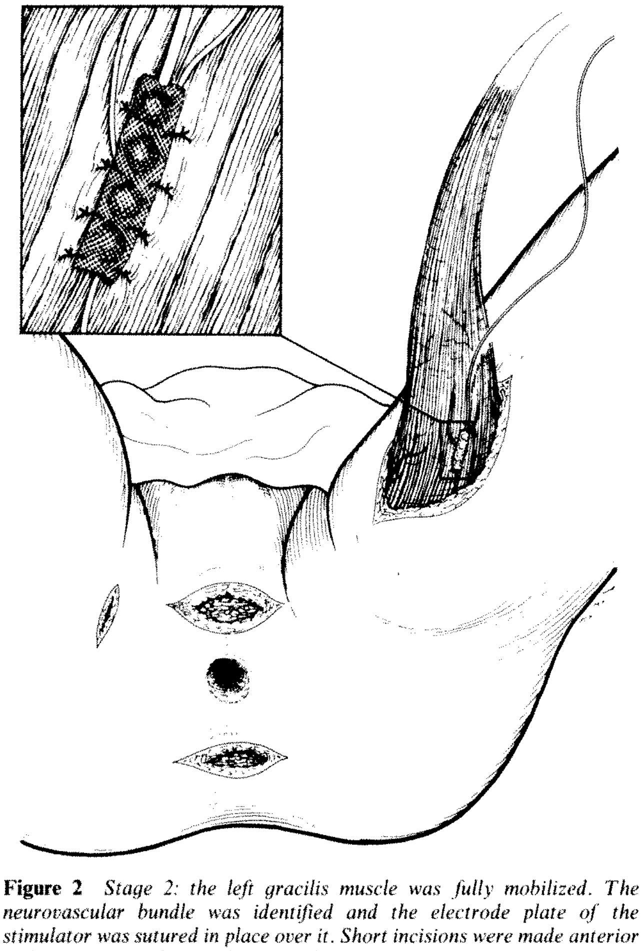

Figure 2 *Stage 2: the left gracilis muscle was fully mobilized. The neurovascular bundle was identified and the electrode plate of the stimulator was sutured in place over it. Short incisions were made anterior and posterior to the pouch–perineal anastomosis*

not to damage the nerve or blood supply of the muscle. Two 1–2 cm curvilinear incisions were then made anteriorly and posteriorly in the perineal skin about 1·5 cm from the ileoperineal anastomosis (*Figure 2*). A circumferential subcutaneous tunnel was created around the efferent spout of the pouch subcutaneously and the gracilis muscle was drawn down from the thigh and passed in a clockwise direction around the neoanal canal (*Figure 3*). The tendon of the muscle was sutured to the opposite ischial tuberosity with the left leg adducted so that the muscle sling was tightly applied around the neoanal canal. The muscle was stimulated once again to ensure that it produced an adequate contraction capable of occluding the anal canal. The stimulator wires were connected to the receiver of a Medronic 3522A (Medtronic Inc.) stimulator (*Figure 3*). The receiver was positioned in a subcutaneous pocket overlying the 8–9th ribs in the midclavicular line.

Postoperative course and physiological investigations

The patient was confined to bed for 5 days with both legs adducted. His recovery was uneventful and, after the 5th postoperative day, he was gradually mobilized, being discharged home on the 7th postoperative day. One month after discharge he was investigated in the anorectal physiology laboratory. The Medtronic 3522A was used to activate the receiver and stimulate the muscle. A Gaeltec (Gaeltec Ltd, Dunvegan, Isle of Skye, UK) microtransducer pressure probe within the neoanal canal was used to record sphincter contraction. The stimulator output voltage and frequency were increased until a fused tetanic contraction was elicited. The minimum stimulus frequency which resulted in a fused tetanic contraction was about 25 pulses per second. After an initial short peak, the pressure in the neoanal canal fell to a plateau which was maintained for 2 min. A saline stress test was performed by infusing physiological saline at a rate of 77 ml/min through a catheter placed in the neorectum. Without stimulation, leakage occurred after the infusion of 32 ml. With tetanic activation of the neosphincter, leakage occurred after 45 ml.

The patient was instructed to use the stimulator for 24 h per day at a frequency of 2 pulses per second and at a voltage that elicited a perceived

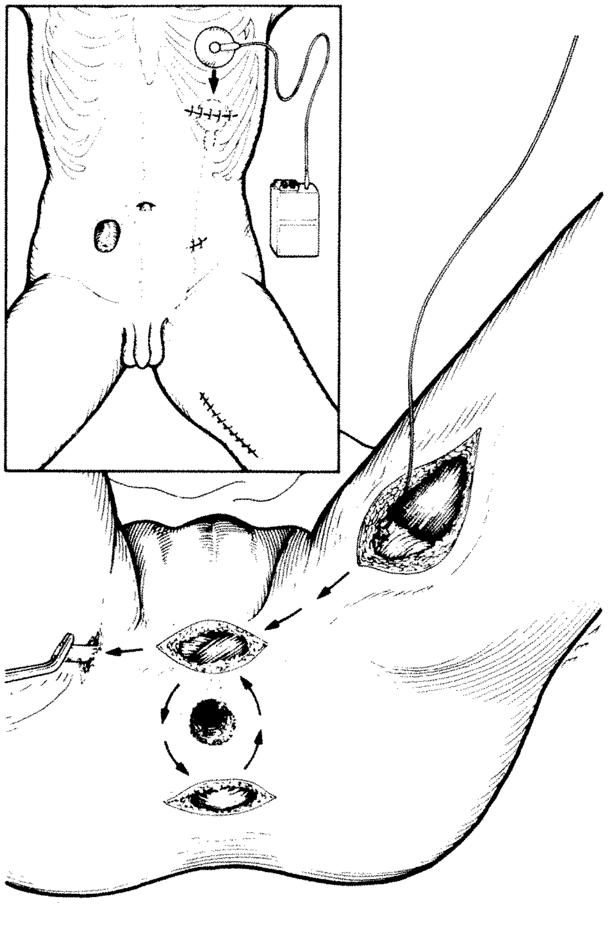

Figure 3 *Stage 2: the gracilis tendon was drawn down and round the efferent spout of the ileal pouch and sutured to the right ischial tuberosity so that when stimulated the 'neoanal canal' was occluded. Inset: the stimulator wires were connected to the receiver of the stimulator which was positioned in a subcutaneous pocket overlying the 8th and 9th ribs anteriorly. The transposed muscle was stimulated by positioning the transmitting aerial of the external stimulator over the receiver. Note the covering ileostomy which was closed 2 months after Stage 2*

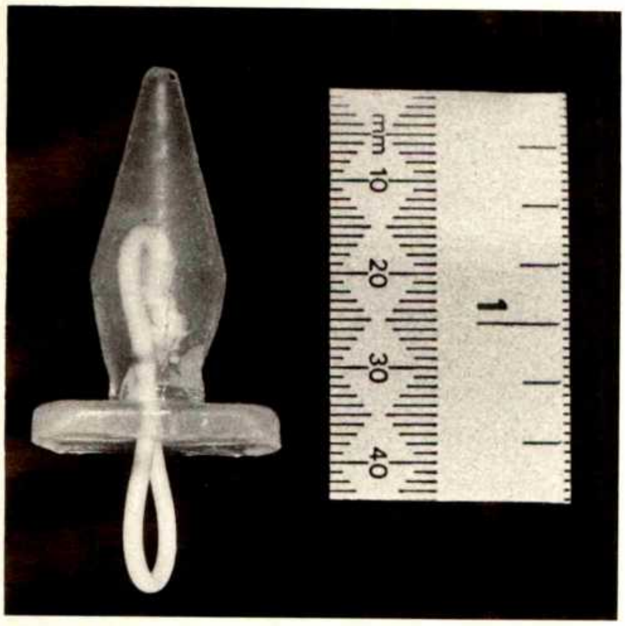

Figure 4 *The Silastic® plug, which was inserted into the neoanal canal and on which the neoanal sphincter contracted to produce continence*

contraction. After 6 weeks of continual stimulation it was found that the muscle was only contracting intermittently. The fault was localized to the electrodes on the neuromuscular bundle. A re-exploration of the electrode site was performed. It was found that part of the electrode plate had come away from its original position. The electrode was repositioned and sutured in place. The patient made an uneventful recovery and continual low frequency stimulation was recommenced on the 6th postoperative day.

Six weeks after the re-exploration he was reinvestigated. The fusion frequency was now 18 pulses per second and the pressure plateau was maintained for 24 min. Leakage occurred after the infusion of 23 ml of saline into the neorectum without sphincter activation, but with tetanic sphincter activation leakage occurred after the infusion of 90 ml. The decrease in the fusion frequency, the increase in duration of the plateau of pressure increase and the increase in volume to leakage during the saline stress test suggested that conversion from rapid twitch to slow twitch muscle had commenced.

The continence mechanism was also tested using a semisolid synthetic 'stool' consisting of oatmeal, barium sulphate and water[4]. When 120 ml of this stool was infused into the pelvic pouch a feeling of fullness was produced. The patient was allowed to be ambulant, but some leakage of stool occurred. As a result, a Silastic® (Dow Company, Reading, UK) 'plug' was devised (*Figure 4*) that fitted into the neoanal canal so that when the stimulator was turned to a subtetanic frequency the neosphincter gripped the plug and it could not be withdrawn easily. The patient was tested again with artificial stool. The plug remained in place overnight for a 16-h period; total continence was achieved throughout the period. The ileostomy was then closed.

Result

Two days after ileostomy closure the patient passed ileal fluid through the neoanal canal. The plug was then inserted and the patient was instructed to use the stimulator for periods of 2 h, after which it was switched off and the pouch evacuated. The patient was able to void spontaneously and empty the pouch completely after the stimulator was switched off and the plug removed. The interval during which the stimulator remained on continually was gradually increased until evacuation was only performed 4–6 times per day. The patient did not experience any discomfort from the presence of the plug which he was able to easily remove and insert at will when the stimulator was switched off.

Three weeks after ileostomy closure he developed small bowel obstruction which did not respond to conservative measures. A laparotomy was performed and an adhesion which had caused a volvulus of the proximal jejunum was found and divided. He made a rapid recovery from this procedure and the above regimen was reinstituted. He was discharged home 14 days after the laparotomy and was fully continent, evacuating the pouch 2–3 times per 24 h. This situation was maintained for 3 months. However, during this period he developed extensive perianal warts which had been a problem in the past. He found it increasingly difficult to insert the silastic plug. This eventually resulted in faecal seepage, his perineal warts became very inflamed and a defunctioning loop ileostomy was re-established. The patient requests that this is closed once the warts have been successfully treated.

Discussion

In this paper we report for the first time a procedure which reconstructs both a neoanorectum and neoanal sphincter mechanism in a patient who had previously undergone proctocolectomy. We have shown that the operation is feasible; the patient was continent and able to void spontaneously, provided the stimulator was turned off and the plug removed. The reconstruction of a new anorectal mechanism required various factors to be fulfilled. The loss of the rectum means there is no storage organ. This was the reason that Valiente and Bacon[5] first in animals, and then Parks and Nicholls[1] in man, constructed an ileal pouch in the original operation of restorative proctocolectomy. We have taken this factor into account and used a triplicated pouch with a short efferent spout of 1·0 cm to replace the rectum. The short length of the spout was considered important as a longer efferent limb may have prevented spontaneous evacuation[6]. Unlike both Parks and Nicholls and Valiente and Bacon, we had to anastomose our neorectum to the perineal skin and not the anal canal.

In order to replace the anal sphincter it is necessary to have a structure which possesses resting tone and is able to mount a sustained maximum contraction capable of resisting intra-abdominal pressure. In addition, such a neosphincter needs to retain its ability to dilate and stretch so that evacuation can proceed. Previous work in animals had suggested that chronic low frequency electrical stimulation of rapid twitch muscle would convert it to a slow twitch muscle[7,8]. We surmised, therefore, that when this was applied to the transposed human gracilis its subsequent conversion would enable it to function as a sphincter. In a series of animal studies[9] we showed that this could be achieved, and in the present patient these results were confirmed. After 6 weeks of low frequency stimulation the neosphincter fusion frequency was decreased as shown by our physiological tests, suggesting that conversion of rapid twitch to slow twitch muscle had commenced. As a result, the neosphincter was able to maintain sufficient tone for it to grip the intra-anal plug for a long period of time without fatigue, provided the stimulus remained subtetanic. Even without the plug, a maximum tetanic contraction occluded the anal canal completely but fatigue intervened after several minutes and some leakage occurred. After the stimulus ceased and the plug was removed the muscle relaxed sufficiently to allow complete evacuation to occur. It might be expected that in the absence of the entire anorectum the patient would experience no sensation of impending defaecation. This was not the case; the desire to defaecate, although not entirely normal, was experienced by the patient as a sense of fullness in the lower abdomen. Whether this sensation was mediated through receptors which are believed to be present in the muscles of the pelvic floor can only be surmised[10,11]. Despite some sensation being present, discrimination of flatus and faeces was not possible. This is hardly surprising as the sensitive anal canal mucosa was entirely replaced by the relatively crude ileal mucosa, which lacks the specialized sensory apparatus present in the normal anal canal[12].

We would stress that the operation has been developed by a multidisciplinary team, including a neurophysiologist and neurosurgeon, both of whom had extensive previous experience with the neurostimulator[13]. This we regard as a prerequisite for the progress achieved. Whilst the patient ultimately needed a defunctioning ileostomy he remained completely continent for 3 months. The ileostomy was required because he developed severe perianal warts which prevented satisfactory insertion of the Silastic plug. The substantial improvement in the patient's lifestyle before this complication was underlined by his desire to have the stoma closed once the warts are eradicated. Clearly this is a technique which needs further development. The purpose of this report is to demonstrate the feasibility of the procedure. Many questions need to be answered before it could become more widespread. We have to determine its reproducibility, its indications, and its long-term reliability. The stability of the electrode placement must be determined. Sepsis might be considered a potential problem because this has marred the success of other procedures which have relied on the implantation of foreign material to treat incontinence. As all the foreign material in our procedure is implanted well away from the perineum, and provided strict asepsis is adhered to during the perioperative period, we do not envisage any greater sepsis rates than those achieved with the implantation of cardiac pacemakers and stimulators used for pain.

We believe that the technique may in the future be an alternative for those patients with ulcerative colitis and familial adenomatous polyposis who have or require a permanent ileostomy, and are unsuitable for conventional restorative proctocolectomy. It it also obvious that a similar technique could be applied to selected patients who have had or require an abdominoperineal excision of the rectum for whatever reason. Similarly, the stimulated transposed gracilis when used alone could restore continence in incontinent patients who have an intact but deficient anal sphincter and in whom a conventional operation has failed or is not indicated. Indeed the latter appears to be the case from our initial data[14].

It must be pointed out that the procedure described is not without risk. If failure occurs the pouch may have to be dispensed with and the patient would lose 40–60 cm of terminal ileum with the concomitant problems associated with that loss. This complication is, however, also applicable to conventional restorative proctocolectomy. Nevertheless, our patient suffered some morbidity, and, whilst we are confident this can be reduced in future, the operation can only be offered at present to highly motivated individuals. Despite the problems we believe that this procedure could eventually eliminate the need for permanent stomas for the majority of patients.

Functional closure of the femoral canal revealed by computed tomographic scanning

The lacuna vasorum contains, as well as the external iliac vessels, a space called the femoral canal which allows pulsation and other changes in the diameter of the two vessels. The canal is closed by a connective tissue septum which is too weak to prevent a herniation alongside the vessels. The functional closure of the canal was investigated by artificial augmentation of the intraluminal pressure of the vein in five specimens and by computed tomographic (CT) scanning during a Valsalva manoeuvre in ten normal persons. In the abdomen the intraluminal and extraluminal pressures are raised in parallel, with no consequence for the diameter of the vessels. In the area of the lacuna vasorum the intravenous pressure is conveyed down to the first competent valve which is located 0·5 cm distal to the inguinal ligament, while the extraluminal pressure is reduced to normal. At each rise of the intra-abdominal pressure the vein will therefore bulge and exactly fill the empty space of the femoral canal thus preventing herniations by an on-demand mechanism. By CT scanning it was found that the vein in the femoral canal increased its diameter 2·5–3·0 times during the Valsalva manoeuvre.

Keywords: Canalis femoralis, hernia, computed tomographic scanning, functional anatomy

The abdominal cavity is a pressure area, out of which several openings lead. At each opening there is a mechanical problem of allowing free passage for the normal content of the canal on desired occasions without letting unwanted content or structures pass through or herniate alongside.

The mechanical problem is different at each site depending on the functional demands, and active sphincters as well as passive mechanisms are employed. The sites where vessels enter or leave the abdominal cavity are guarded by passive mechanisms, for example the hiatus of the aorta and the inguinal canal, with its pampiniform plexus, are closed primarily by their oblique course through the abdominal wall, while the foramen of the inferior vena cava is secured by adherence of the central tendon of the diaphragm to the periphery of the vein.

The external iliac artery and vein are large vessels which leave the abdominal cavity at a right angle to the abdominal wall and with ample room around them in the femoral sheath. The vessels are located in a common sheath which medially contains a space, the femoral canal. The canal is filled with areolar tissue and lymphatics, thereby allowing changes in the diameter of the two vessels within the limits of the sheath[1–3]. The abdominal end of this canal is covered by a delicate septum, a continuation of the fascia transversalis, but this alone can barely resist the intra-abdominal pressure[3]. The mechanism by which herniation at this site is resisted is unexplained.

With the first competent valve of the venous system of the leg located at the inguinal ligament just outside the abdominal pressure area[4], the mechanism of closure could be that the vein becomes distended by increased abdominal pressure and thereby exactly fills the canal, closing it when necessary. The soft tissues in question are structurally defined well enough to be outlined by computed tomographic (CT) scanning, and it was decided to combine an investigation on autopsy material with functional *in vivo* tests performed with the CT scanner.

Materials and methods

The external iliac and femoral veins were studied in five cadavers at autopsy. The inguinal ligament and the inner ring structures of the femoral canal were left untouched. Through a cannula connected to a pressure gauge, saline was injected into the external iliac vein under a pressure of 80–100 mmHg, which is comparable to the intra-abdominal pressure during a cough or straining manoeuvre. The enlargement of the vein was measured, and the fullness of the femoral canal was registered with a probe before and after applying the pressure.

The veins were then excised, and histological sections were made of sectors located proximally, deep to, and distally to the inguinal ligament. The sections were stained with haematoxylin and eosin, and for elastin and collagen fibres.

The experiment on the vein was repeated with CT scanning on ten living subjects who had given their informed consent. The subjects had normal inguinal regions. There were five men and five women aged 30–40 years. Two scans were made of each person in the supine position, one scan during quiet breathing and one during a Valsalva manoeuvre where a high intra-abdominal pressure was established for approximately 20 s. In one case longitudinal scans through the vein were constructed by the computer from 15 transverse sections separated by 5-mm intervals.

Results

In each of the five cadavers the first competent valve in the femoral vein was located 0·5 cm distal to the inguinal ligament. The wall immediately proximal to the valve, the so-called sinus of the valve, was thin and lacked a substantial tunica intima and media, which otherwise are pronounced in the iliac and femoral veins. When the pressure was applied to the vein the sinus was enlarged like a bulb sufficient in size to occupy the free space of the femoral canal without impinging on its margins. No space then remained in the canal alongside the vein (*Figures 1a* and *1b*).

By CT scanning, the content as well as the limits of the femoral sheath were clearly demonstrated (*Figure 2*). During the Valsalva manoeuvre the vein deep to the inguinal ligament increased its diameter from approximately 6 × 9 mm to 10 × 15 mm. The cross-sectional area was thereby increased 2·5–3·0 times, and it was found that the vein was able exactly to fill out the available space in these *in vivo* situations (*Figure 2b*). In three cases no enlargement was found, probably because of unsuccessful co-operation during the moment of radiography.

During the latter the vein creates a functional closure of the femoral canal; 2, femoral artery; 3, inguinal ligament; 4, head of femur*

From the constructed longitudinal scans the one through the middle of the vein was selected (*Figure 3*). This also showed the enlargement of the vessel at its transition from intra-abdominal to extra-abdominal position.

Discussion

The femoral sheath is unique in letting its content, the femoral artery and vein, pass through the abdominal wall at a right angle to the wall, with ample room alongside and with no sphincter muscle to close it off. The femoral septum which covers the internal ring is delicate and has no fascial back-up to carry the pressure as in the inguinal region, where the fascia transversalis is supported anteriorly by the external oblique aponeurosis.

The present investigation shows that the part of the vein that lies deep to the inguinal ligament expands its cross-section at each rise in intra-abdominal pressure enabling it exactly to occupy the funnel-shaped femoral sheath. The inner ring of the femoral canal is thus closed off by an on-demand mechanism, and the role of the septum seems more to be a curtain that can be drawn aside.

While the diameter of the intra-abdominal veins is almost constant because the intraluminal pressure follows the pressure

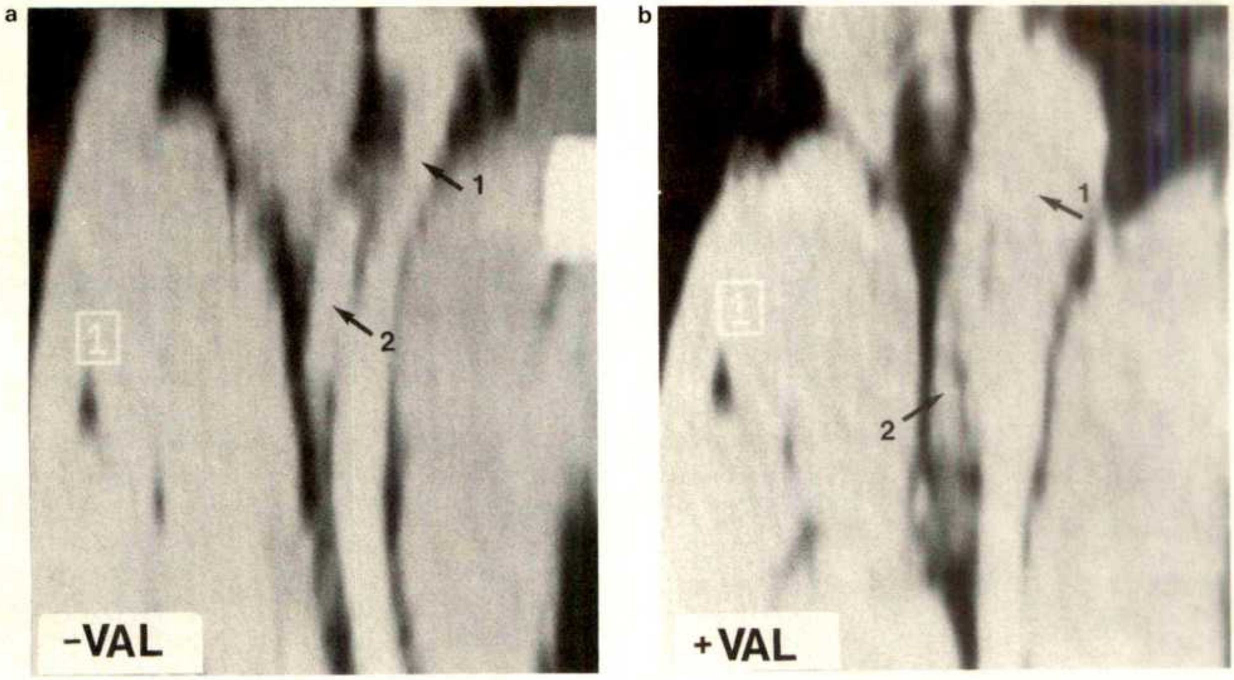

Figure 3 *Frontal sections.* **a** *Constructed longitudinal computed tomographic scan through the middle of the vein as it passes through the lacuna vasorum.* **b** *With increased intra-abdominal pressure, a longitudinal swelling is created comprising the distal part of the external iliac vein (1) and its transition to the femoral vein. The artery (2) keeps its diameter unchanged*

of the abdominal cavity, the conditions deep to the inguinal ligament are different. In this transitional zone the intraluminal pressure is conveyed down to the first competent valve in the femoral vein, while the pressure outside this sector of the vein is reduced to normal. The thin-walled vein will therefore bulge in this area.

Excessively increased abdominal pressure, enlargement of the femoral canal, and/or a functional decrease of the diameter of the vein are said to be predisposing factors for a femoral hernia[2,5–8]. To this we can add that an incompetent valve in the proximal part of the femoral vein will be another risk as it makes the bulging of the vein less likely.

It has been shown that the external iliac vein in 15–20 per cent of cases is equipped with a competent valve[4,9] (*Figure 4*). If that is combined with an absent or incompetent valve in the femoral vein, a reverse situation to the normal is created, i.e. a raised intra-abdominal pressure will squeeze the blood out of the vein in the femoral sheath and force the vein to collapse, thereby enlarging the inner ring of the femoral canal. Finally, it should be noted that this is compatible with the fact that competent valves are much more common in the right iliac vein and that right-sided hernias are twice as common as left-sided ones[4,10].

We have concluded that raised intra-abdominal pressure creates a local swelling of the vein in the femoral canal sufficient in size to close the canal and protect against herniation. The swelling which is produced by the intraluminal pressure is dependent on the existence of a competent valve in the proximal femoral vein.

Limb conservation for soft tissue sarcomas of the shoulder and pelvic girdles

Fifty-five patients with soft tissue sarcomas of the shoulder and pelvic girdles were treated between 1982 and 1987 with a consistent policy of limb conservation, using a wide variety of excisional and reconstructive surgical techniques and radical radiotherapy. Actuarial 5-year overall survival was 75 per cent for patients with low or intermediate grade tumours, and 38 per cent for those with high grade tumours (log rank test, $P<0{\cdot}05$*). Five-year local recurrence rates were 32 per cent for low or intermediate grade tumours, and 48 per cent for high grade tumours (log rank test, not significant). Multivariate analysis of the following risk factors for overall survival was performed: age, sex, tumour site, diameter, grade, inadequate surgical margins and local recurrence. Age over 55 years and high tumour grade emerged as independent prognostic variables for survival. Forequarter or hindquarter amputations were undertaken in seven of the 55 patients for local recurrence following previous limb-conserving surgery and radiotherapy. Local failure was not always salvaged by major amputation; satisfactory proximal tumour clearance was achieved in only two of seven patients undergoing major amputation; four of the seven patients developed stump recurrence, three of whom died with uncontrolled local disease. Meticulous attention to surgical and radiotherapeutic technique is required to minimize the incidence of local recurrence while maintaining satisfactory limb function.*

Soft tissue sarcomas of the shoulder and pelvic girdles are a particularly difficult group of tumours to manage. They are frequently large and deeply situated at initial presentation, and are associated with a poorer prognosis than sarcomas situated more distally on the limbs[1]. Limb-sparing surgery is technically challenging: the tumours often lie in relation to major neurovascular bundles, and adequate proximal margins can be difficult to obtain when the tumour lies adjacent to the chest wall or pelvis. The factors that may make limb-sparing surgery with satisfactory tumour clearance impossible, such as extension of tumour above the inguinal ligament or across the midline, are the same factors that militate against performing a satisfactory amputation.

Since 1982 we have treated 55 cases of soft tissue sarcoma of the shoulder and pelvic girdles with a consistent policy of combined modality limb-conserving therapy, and have undertaken a prospective study of prognostic variables. In this article we review some of the technical aspects of limb-sparing surgery and amputation in the management of these tumours, and the factors associated with local or distant failure.

Patients and methods

Fifty-five patients with soft tissue sarcomas arising within the tissues of the shoulder or pelvic girdles have been referred to this unit for definitive management since 1982. Patients with primary bone neoplasms, childhood embryonal rhabdomyosarcoma, or tumours considered to have arisen within the thigh or arm have been excluded from this report.

Of the 55 patients, 43 were referred with previously untreated primary soft tissue sarcomas, usually following an incision biopsy or limited excisional surgery elsewhere. Twelve of the 55 patients were referred for management of locally recurrent disease following initial definitive management at other institutions. The median age of the patients was 43 years (range 11–84 years), and there were 29 male and 26 female patients. The four patients with rhabdomyosarcoma were over 18 years of age. Our policy was to undertake limb-sparing surgery rather than amputation whenever possible, reserving amputation for otherwise untreatable local disease.

The margins of surgical clearance were recorded as radical, wide, marginal or intracapsular according to the criteria described by Enneking *et al.*[2]. Patients with high grade tumours, or with low or intermediate grade tumours in whom a marginal or intracapsular excision had been performed, received postoperative radical radiotherapy to the tumour bed and 'at risk' surrounding tissues (23 of 43 previously untreated patients). Seven of the previously untreated patients received palliative irradiation for inoperable tumours, and two received preoperative irradiation for bulky tumours. Eleven of the previously untreated patients did not receive radiotherapy for a variety of reasons (four low grade tumours, three radiation-induced tumours, two with concomitant metastases, one wound breakdown, one child). Of the 12 recurrent cases, six received radical adjuvant postoperative radiotherapy, five had received previous irradiation which precluded further radiotherapy and one had preoperative radiotherapy.

The patients have been followed up for a median of 3 years (range 1·5–7·0 years). Actuarial local recurrence-free survival and overall survival were calculated according to the method of Kaplan and Meier[3], and the log rank test of statistical significance was used to compare differences between stage subgroups[3]. The tumours were graded according to a three-point scale into 'high', 'intermediate' or 'low' grade by one pathologist (C.F.), but intermediate and low grade tumours have been considered together in this anlaysis because no significant survival difference was found between these two groups. The following factors were entered into a multivariate analysis of risk factors for overall survival for the 43 patients presenting with previously untreated disease: age, sex, tumour grade (high *versus* low/intermediate), site (shoulder *versus* pelvis), maximum tumour diameter, surgical margins (radical/wide *versus* marginal/intracapsular) and local recurrence. Adjuvant radiotherapy was not analysed as a separate factor as it had been given consistently to high risk cases. Similarly, the influence of adjuvant chemotherapy was impossible to determine because of the

heterogeneous nature of the regimens employed. The data were analysed by the Cox proportional hazards technique[4].

Results

The sites of the tumours are shown in *Table 1*, the most common sites being buttock, groin or femoral triangle, and periscapular tissues. Two intrapelvic tumours were included within the definition of 'pelvic girdle' because they were situated within the iliopsoas muscle and were potentially resectable by hindquarter amputation. *Table 2* lists the histological subtypes. There were 37 high grade, ten intermediate and eight low grade tumours. The mean tumour diameter was 10·5 cm (median 10 cm, range 1–30 cm).

The surgical procedures performed for the previously untreated cases are listed in *Table 3*. In eight cases the tumour was considered to be inoperable, and biopsy alone was performed. In five patients a re-excision of tumour bed was performed after limited excisional surgery elsewhere; three of these five patients had histological evidence of residual disease. Twenty-six patients had major soft tissue resections; compartmental resection was performed when possible, but was not feasible when the tumour had arisen within the axilla or femoral triangle, or had infiltrated outside the confines of its compartment of origin. The margins of excision are shown in *Table 4*. Radical or wide tumour resection was possible in only 15 of 35 (43 per cent) operable primary tumours. Two patients had a major nerve excised in continuity with the tumour (femoral and median) and one patient underwent excision of the external iliac vein without vascular reconstruction or significant postoperative morbidity.

Two patients had partial pelvic bony resections, in which a section of ilium was excised in continuity with the specimen to obtain wide tumour clearance without the need for hemipelvectomy; in both cases preoperative computed tomography had suggested invasion through the periosteum. Two patients had scapulectomy for bulky periscapular tumours, and wide clearance was achieved while preserving a functional upper limb.

Overall survival for the previously untreated tumours is shown in *Figure 1*. The probability of 5-year survival was 75 per cent for low/intermediate grade tumours and 38 per cent for high grade tumours (log rank test, $P < 0{\cdot}05$). The probability of local recurrence for the previously untreated tumours is shown in *Figure 2*. The probability of a local recurrence by 5 years was 32 per cent for low/intermediate grade tumours and 48 per cent for high grade tumours (log rank test, $\chi^2 = 0{\cdot}25$, not significant). Of the 43 patients with previously untreated primary soft tissue carcinomas, 14 had a local recurrence of whom eight had no evidence of metastatic disease at the time of local recurrence.

Table 5 *Multivariate analysis of risk factors for overall survival*

Factor	Relative risk	Reduction in log likelihood
High grade	15·3 (1·6–141·0)	$\chi^2 = 6{\cdot}8$ $P = 0{\cdot}009$
Age over 55 years	5·8 (1·3–26·5)	$\chi^2 = 4{\cdot}1$ $P = 0{\cdot}043$
Site (pelvis)	2·9 (0·6–13·8)	$\chi^2 = 2{\cdot}0$ $P = 0{\cdot}16$
Local recurrence	2·1 (0·5–12·1)	$\chi^2 = 1{\cdot}64$ $P = 0{\cdot}2$
Margins of clearance (inadequate)	1·7 (0·3–8·5)	$\chi^2 = 0{\cdot}62$ $P = 0{\cdot}4$

Values in parentheses are 95 per cent confidence intervals

The factors significantly associated with impaired overall survival on multivariate analysis were: high tumour grade ($P = 0{\cdot}009$) and age over 55 years ($P = 0{\cdot}043$; *Table 5*). Age did not emerge as an independent risk factor when tumour-specific mortality was analysed.

A total of 53 surgical procedures was performed for local recurrence in 26 patients (12 patients referred for management of local recurrence, plus 14 of 43 patients having local recurrence following primary treatment at this institution). The procedures performed are shown in *Table 6*. Of the 53 procedures, 23 were definitive limb-sparing resections for recurrent disease, including chest wall resection in two patients (both repaired with polypropylene mesh and a myocutaneous flap) and an abdominoinguinal excision of recurrent fibrosarcoma infiltrating from groin to external iliac vessels in one patient, using the Karakousis approach[5]. Three patients with recurrent groin disease required myocutaneous flap repair using tensor fasciae latae, rectus abdominis and a latissimus dorsi microvascular free flap, respectively.

Major amputation was performed in seven patients: two forequarters and five hindquarters. The amputations were all undertaken for uncontrolled local recurrence after previous limb-sparing surgery and radical radiotherapy. Amputation was performed in the presence of known distant metastases in two patients for palliation of ulcerating local disease. In five patients the margin of clearance obtained at amputation was considered to be 'marginal' or 'intracapsular', and in only two patients was it considered to be 'wide'; none was radical. Five of the seven amputees have died, at a median of 4 months (range 3–12 months) from the date of amputation. Three of these amputees died with further local recurrence within the amputation stump; in two of these patients no clinical evidence of distant metastatic disease was present, suggesting that they may have died from rather than with uncontrolled local disease. Of the two amputees who are alive, 12 and 30 months after amputation respectively, one has had a stump recurrence treated by marginal surgical excision and both have metastases. A total of four amputees have thus suffered a stump recurrence.

Discussion

Limb-sparing surgery combined with radical preoperative or postoperative radiotherapy has become the standard treatment for soft tissue sarcomas of the limbs and limb girdles in recent years. The results of this approach in terms of local control and survival have been shown to be equivalent to those obtained by radical surgery alone in several major retrospective series[6–10]. A prospective randomized trial of limb-sparing surgery from the National Cancer Institute in the USA demonstrated an increased risk of local recurrence in high grade sarcomas of the extremities treated by such surgery compared with amputation, but no impairment of overall survival was seen[11]. Several centres add chemotherapy to the combined modality treatment of these tumours (for example, with preoperative intra-arterial Adriamycin®, Farmitalia Carlo Erba Ltd., St. Albans, UK[12], or with postoperative adjuvant combination chemotherapy regimens[7]), but the degree of survival advantage or improved local control conferred by chemotherapy is still unclear[13].

The risk factors associated with poor overall survival (grade and age) in our multivariate analysis are in accordance with those reported by other authors for soft tissue sarcomas of the limbs[6,9,11,14–18]. Tumour size and inadequate surgical margins, which have correlated with survival in other series, did not influence survival in our own analysis, and local recurrence did not emerge as an independent risk factor. This may be a reflection of the value of adjuvant irradiation in the treatment of primary and recurrent disease.

Limb-sparing combined modality therapy is particularly difficult in the management of tumours in the shoulder and pelvic girdles. In only two of the 43 cases reported here was radical excision of a primary tumour possible; in both cases the tumours had arisen within the gluteus maximus muscle and a compartmentectomy could be performed. Wide excision of bulky high grade tumours still proved possible without amputation by using the techniques of scapulectomy in two patients and partial pelvic resection in two patients. However, in the majority of primary tumours (20 of 43) the excision was marginal or intracapsular, and eight out of 43 patients had tumours that were considered to be inoperable on the basis of preoperative clinical examination and computed tomography.

Table 6 *Surgery for local recurrence*

Procedure	*n*

Soft part resection	20
Chest wall resection	2
Abdominal hysterectomy and oöphorectomy	1
Small bowel resection	1
Karakousis operation	1
Forequarter amputation	2
Hindquarter amputation	5

For locally recurrent sarcomas, the situation was even more difficult. The tumour boundaries tended to be indistinct, and infiltration into adjacent muscle compartments, bone, joints or other tissues often made further limb–sparing surgical excision impossible. However, in contrast to more distally situated limb sarcomas, in which control of local failure can usually be achieved by amputation through non-involved tissue at or above the proximal joint, local control by amputation was not always possible. Extension of tumour across the midline, into the pelvis, or into the iliopsoas muscle made hindquarter amputation impossible for two patients with local recurrence, and only palliative for another. Similarly, the finding of recurrent tumour around the brachial plexus at forequarter amputation rendered this a palliative procedure for one patient.

Surgical options less mutilating than forequarter or hindquarter amputation, such as the Tikhoff–Lindberg procedure[19] (in which the scapula, clavicle and head of humerus are excised leaving the distal limb with its neurovasculature intact) or internal hemipelvectomy (in which the hemipelvis is removed but the lower limb with its neurovascular connections is preserved), may be appropriate for some primary bone tumours or for some soft tissue tumours of the proximal limb or limb girdle[20–23]. None of the recurrent limb girdle soft tissue sarcomas in this series was suitable for such surgical options, as the tumours had infiltrated too widely around neurovascular bundles and limb girdle musculature.

Modified hindquarter amputation was performed in one patient in this series, in whom the iliac bone was sectioned horizontally at the level of the sciatic notch thus preserving the sacroiliac joint and posterior ilium[21]. This involves an easier dissection and leaves a better 'shelf' for supporting a prosthesis, but is possible only in carefully selected patients. One of the four patients having a classical hindquarter amputation required an anterior skin flap based on the external iliac vessels, as the tumour and previous surgical scar had compromised the buttock skin[24,25].

The high incidence of stump recurrence following forequarter or hindquarter amputation reflects the difficulty of achieving satisfactory proximal tumour clearance. Adjuvant perioperative radiotherapy to the stump has been advocated[18], but was not possible in this series because of the proximal extent of the original radiotherapy fields.

Soft tissue sarcomas of the shoulder and pelvic girdles require meticulous attention to surgical and radiotherapeutic technique to minimize the incidence of local recurrence while maintaining satisfactory limb function. Expertise in a wide variety of excisional and reconstructive procedures is essential. Local failure may not be salvageable by subsequent amputation.

Arteriogram scoring systems and Pulse Generated Run-off in the assessment of patients with critical ischaemia for femorodistal bypass

D. J. A. Scott, G. Hunt*, J. D. Beard, G. G. Hartnell* and M. Horrocks

Vascular Studies Unit and

Correspondence to:
Mr M. Horrocks

Conventional arteriography is the investigation of choice in patients with critical ischaemia to select the site for the distal anastomosis of a femorodistal bypass. Several arteriographic scoring systems have been devised in an attempt to quantify the run-off. More recently Pulse Generated Run-off and intraoperative peripheral resistance measurements have been proposed as better predictors of early graft patency. Eighty-eight consecutive femorodistal bypass grafts were studied using Pulse Generated Run-off (PGR), conventional and intra-arterial digital subtraction arteriography (DSA) and peripheral resistance measurement. Three widely used arteriographic scoring systems were used to grade the arteriographic run-off. There were significant correlations between the scoring systems and the measured peripheral resistance, although PGR correlated better with peripheral resistance than arteriography ($r_S = -0{\cdot}59$, $P < 0{\cdot}001$). Intra-arterial DSA improved the correlation between the arteriogram scoring systems and the measured peripheral resistance in the distal popliteal artery, but not in single calf vessels. In contrast, PGR correlated much better with peripheral resistance in single calf vessels ($r_s = -0{\cdot}82$, $P < 0{\cdot}001$). We recommend that selection for femorodistal reconstruction be based on a combination of intra-arterial DSA and PGR. PGR will identify patent distal calf vessels not seen on arteriography and determine their continuity with the pedal arch, two features which are essential prerequisites for successful femorodistal bypass.

Keywords: Femorodistal bypass, conventional arteriography, digital subtraction arteriography, critical ischaemia, pulse generated run-off

Since Brooks performed the first femoral arteriogram in September 1923[1], conventional preoperative arteriography has become the investigation of choice in the assessment for vascular reconstruction of patients with critical ischaemia. The development of computerized digital subtraction techniques has improved the visualization of the distal vasculature[2], especially when combined with reactive hyperaemia[3]. Arteriography helps identify patients who may benefit from an improved inflow, either by a proximal reconstruction or by balloon dilatation and it provides the surgeon with information to help select the appropriate vessel and level of the distal anastomosis.

Grafts performed to calf vessels in continuity with the pedal arch have significantly better short- and long-term patency rates than those without such continuity[4-6]. In critical ischaemia, identification of the distal run-off may be hampered by a combination of factors including severe multisegment disease, poor myocardial function and ectatic vessels, all of which lead to rapid layering and sedimentation of contrast media. As a result, the arteriogram may be misleading and may fail to identify patent distal vessels in the lower calf[7]. The identification of patent calf vessels has been improved by Pulse Generated Run-off (PGR)[7], a non-invasive test which gives a semi-quantitative analysis of each of the calf vessels and its relative contribution to the pedal arch.

In an attempt to improve the predictive value of arteriography, various scoring systems have been devised ranging from the simple to the complex[8-11]. More recently, peripheral resistance has been shown to be an excellent predictor of early graft function[12-14] and in this study the PGR and arteriogram scores were correlated with the measured peripheral resistance. The impact of intra-arterial digital subtraction arteriography (DSA) on the prediction of peripheral resistance was also assessed.

Patients and method

Eighty-eight consecutive femorodistal non-reversed vein grafts were performed in 57 men and 31 women of median age 71 years (range 41–87 years). All grafts were performed for critical ischaemia[15]: 37 for rest pain and 51 for tissue necrosis. Twenty-eight grafts were anastomosed to a single calf vessel, nine to the tibioperoneal trunk and the remaining 51 to the distal popliteal artery. Before surgery all patients underwent non-invasive assessment which included Doppler ankle pressures and a PGR study.

Pulse Generated Run-off

The patients were fully rested for 10 min before starting the study. The examination was performed in the supine position with the heels resting on a support. An inflatable cuff was wrapped tightly around the upper calf and rapidly inflated and deflated over a pressure of 300 mmHg at 50 cycles per minute. An assessment of all three calf vessels and the pedal arch was made at the ankle using a 10 MHz hand-held Doppler velocimeter[7] (*Figure 1*). The resultant Doppler waveforms were scored as follows: 2 points for a biphasic wave, 1 point for a monophasic wave and no point for an absent signal (*Figure 1*). Thus a possible maximum score of 6 could be obtained for each leg, and 6 represents an excellent run-off.

0007–1323/89/1202–05$3.00 © 1989 Butterworth & Co (Publishers) Ltd

Arteriography

A routine preoperative conventional arteriogram was performed in all cases. In the latter half of the series (48 cases) conventional arteriography was supplemented by intra-arterial DSA. The calf vessel run-off was reported independently of the PGR score, peripheral resistance and graft outcome. Three arteriographic scoring systems were used.

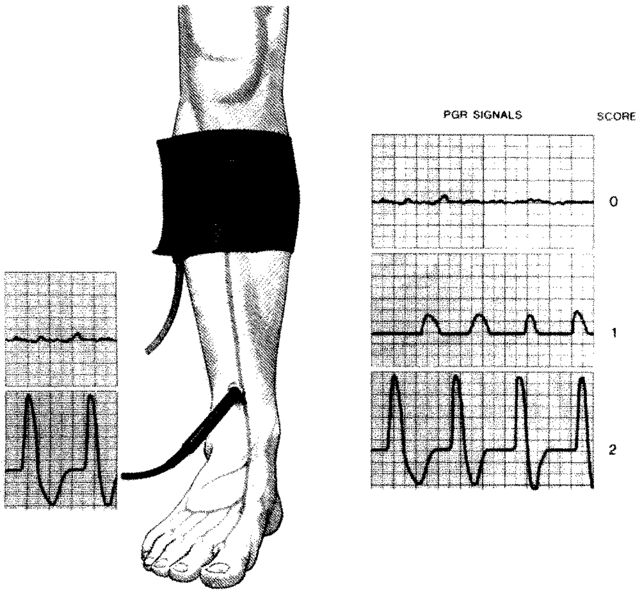

Figure 1 *Pulse Generated Run-off and scoring system. This shows the cuff around the upper calf with a 10 MHz Doppler pencil probe insonating the anterior tibial artery. The top trace shows a non-pulsatile signal and below the same signal augmented by the Pulse Generated Run-off*

Scoring system A. Two points were given to a widely patent vessel to the ankle, 1 point for a diseased but patent vessel to the ankle and no points for an occluded vessel, thus giving a range from 0 to 6, where 6 represents an excellent run-off (*Figure 2a*).

Scoring system B. In this scoring system the calf vessels were assessed over the first 5 cm from their origin. For a normal vessel 2 points were given, 1 point for a diseased vessel with a greater than 50 per cent stenosis and no points for an occlusion[8], giving a possible range of 0 to 6 (*Figure 2b*).

Scoring system C. In an attempt to standardize the various arteriographic scoring systems the Committee on reporting standards of the Society for Vascular Surgery and the International Society for Cardiovascular Surgery (SVS and ISCVS) devised a new run-off grading system which could be applied to any level of the infrainguinal arterial tree. The run-off was assessed at the proposed site of the distal anastomosis. This is a complex scoring system and is well described elsewhere[11]. Essentially the graded scoring system is based upon the patency of the vessel and the relative contribution to the outflow tract. A score of 1 corresponded to an excellent run-off and 10 to a blind segment (*Figure 2c* and *d*).

Operative measurement of peripheral resistance

Peripheral resistance was measured by introducing a newly produced soft 6/8 Fr (Portex®, Portex Ltd, Hythe, UK) tapered end catheter into the vessel chosen for the distal anastomosis (*Figure 3*). A hand infusion of heparinized blood was performed at a physiological pressure of about 80–100 mmHg. Pressure (P) was measured by a pressure transducer and flow (Q) by a recently developed ultrasonic flowmeter[16].

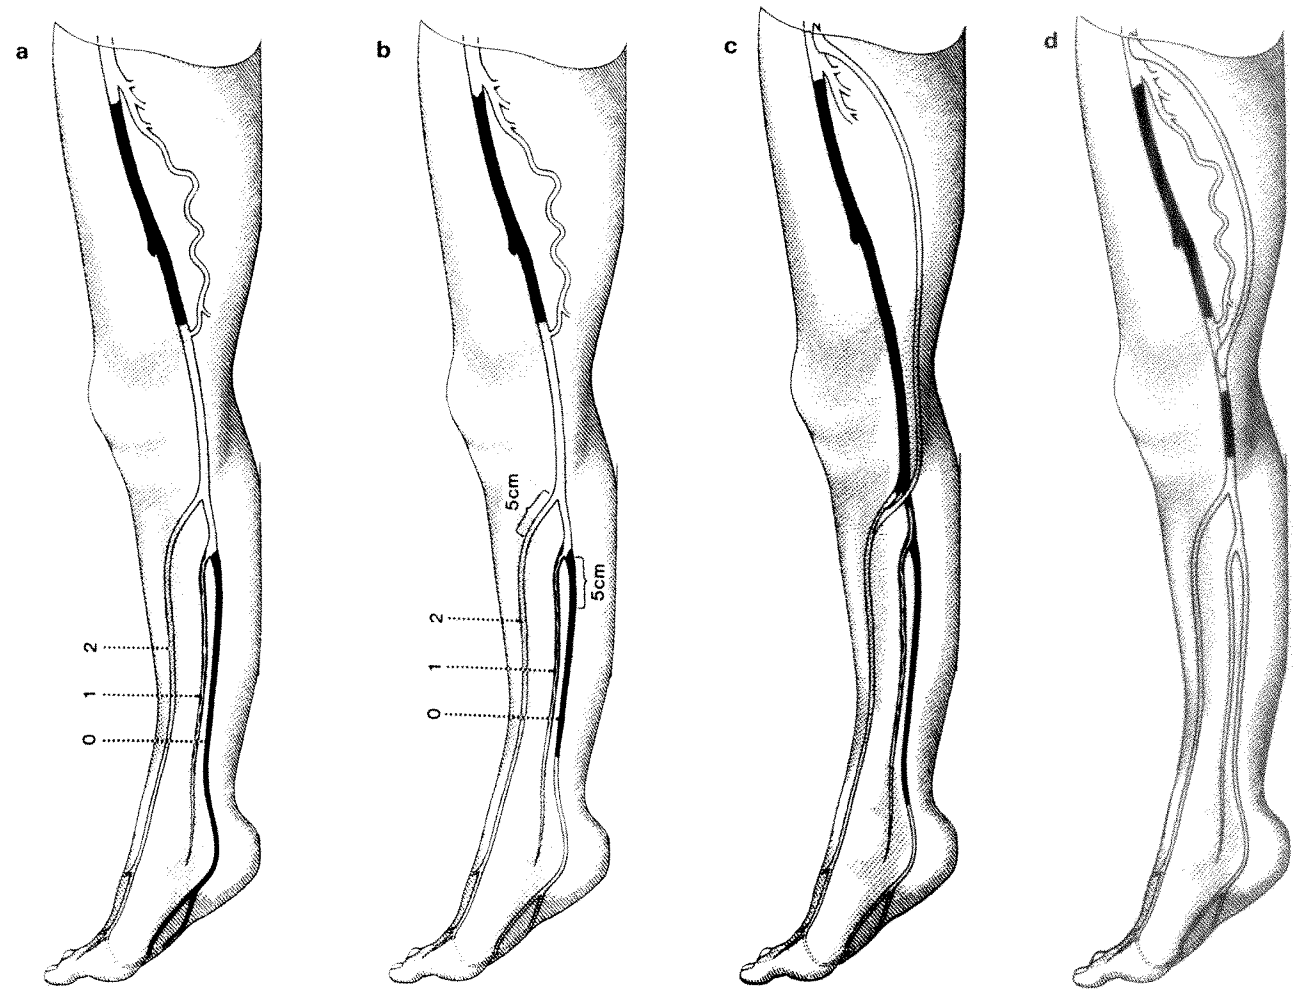

Figure 2 **a** *Arteriogram scoring system A*; **b** *arteriogram scoring system B*; **c** *arteriogram scoring system C (showing a graft anastomosed to a patent anterior tibial artery), score = 1; and* **d** *arteriogram scoring system C (showing a graft anastomosed to a popliteal blind segment), score = 10 poor run-off*

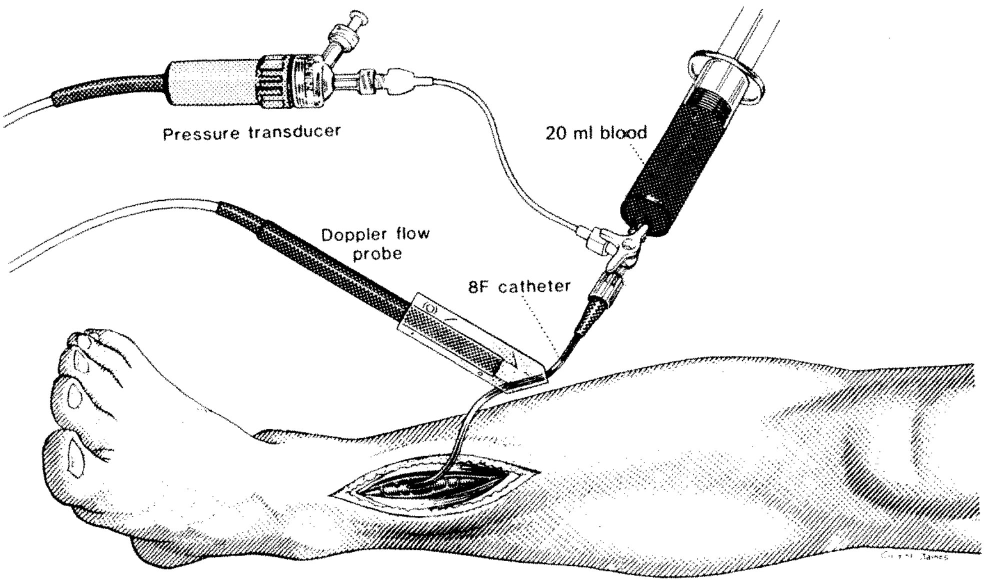

Figure 3 *Method of peripheral resistance measurement. This shows a soft 8 Fr catheter inserted into the distal anterior tibial artery. During the infusion of heparinized blood, pressure is measured by the pressure transducer and flow by the Doppler flow probe linked to the flowmeter*

Table 1 *Spearman rank correlations between peripheral resistance and either Pulse Generated Run-off or arteriogram scoring systems*

Correlation	Pulse Generated Run-off	Score A	Score B	Score C
PR r_S	−0·59*	−0·36*	−0·33*	0·33*

PR, peripheral resistance; * $P<0.001$

Simultaneous recordings of pressure and flow were converted by an Apple 2E (Apple Computer Company, Cupertino, California, USA) microcomputer into peripheral resistance units (PRUs), where:

$$1\ \text{PRU} = 1\ \text{mmHg}/1\ \text{ml blood flow per min}$$

The peripheral resistance was then calculated by subtracting the resistance of the catheter R_C from the total resistance R_T. The catheter resistance R_C was calculated by measuring the pressure and flow during an infusion of heparinized blood through an open ended catheter:

$$\text{Peripheral resistance (PR)} = R_T - R_C$$

Results

Correlation between peripheral resistance and either Pulse Generated Run-off or arteriogram scoring systems

Eighty-eight femorodistal bypass grafts were analysed to determine the value of PGR and the arteriographic scoring systems A, B and C and these values were correlated with the measured peripheral resistance at the time of femorodistal bypass.

There was a significant correlation between the arteriogram scoring systems A, B and C and the measured peripheral resistance (*Table 1*). However PGR correlated much better with peripheral resistance ($r_S = -0.59$, $P<0.001$) than any of the arteriogram scoring systems A, B or C (*Figure 4*).

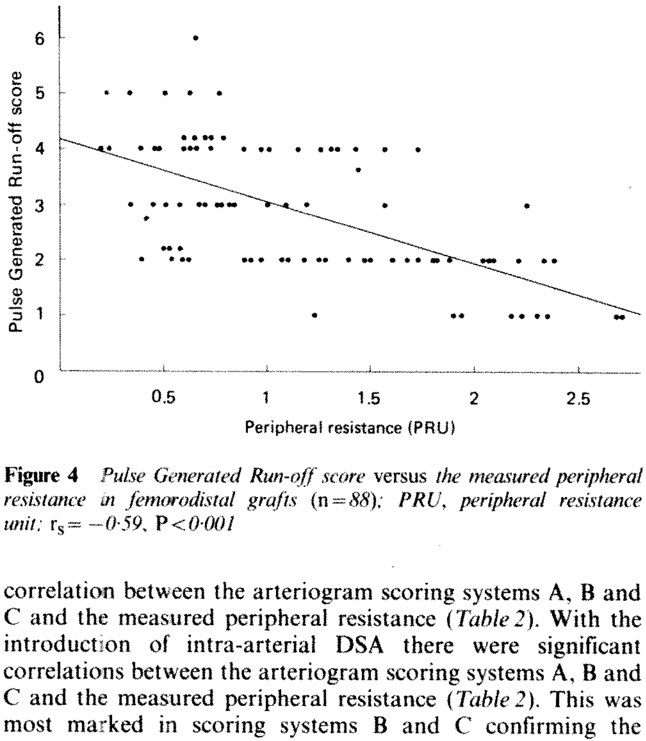

Figure 4 *Pulse Generated Run-off score* versus *the measured peripheral resistance in femorodistal grafts* (n=*88*)*; PRU, peripheral resistance unit;* $r_S = -0.59$, $P<0.001$

Influence of intra-arterial digital subtraction arteriography on the scoring systems

During this consecutive series, intra-arterial DSA became available and was routinely used in the assessment of patients with critical ischaemia. Two groups were subsequently identified and analysed to assess the impact of intra-arterial DSA: group I, conventional arteriography only, 40 patients; and group II intra-arterial DSA, 48 patients.

In the conventional arteriogram group there was a poor correlation between the arteriogram scoring systems A, B and C and the measured peripheral resistance (*Table 2*). With the introduction of intra-arterial DSA there were significant correlations between the arteriogram scoring systems A, B and C and the measured peripheral resistance (*Table 2*). This was most marked in scoring systems B and C confirming the improved visualization of calf vessels using the intra-arterial DSA technique.

In both groups I and II there was a significant correlation between the PGR score and the measured peripheral resistance ($r_S = -0.74$, $P<0.001$ and $r_S = -0.44$, $P<0.001$ respectively). The variability between groups I and II is almost certainly related to the inability of PGR to detect proximal calf vessel disease.

The role of PGR and intra-arterial DSA in determining the site of distal anastomosis

Groups I and II were analysed to assess the role of both PGR and intra-arterial DSA in determining the suitability of patients for either proximal (distal popliteal) or distal calf (single calf vessels) reconstructions.

Proximal calf (distal popliteal) reconstructions. The arteriogram scores A, B and C derived from the intra-arterial DSA

Table 3 *Correlation of peripheral resistance with arteriographic scoring systems in reconstructions to the distal popliteal artery*

Group	*n*	Correlation	Score		
			A	B	C
I (conventional arteriography)	22	PR r_S	−0·25‡	−0·10‡	0·24‡
II (intra-arterial DSA)	29	PR r_S	−0·43*	−0·56†	0·55†

DSA, digital subtraction angiography; PR, peripheral resistance; *$P<0{\cdot}01$; †$P<0{\cdot}001$; ‡not significant

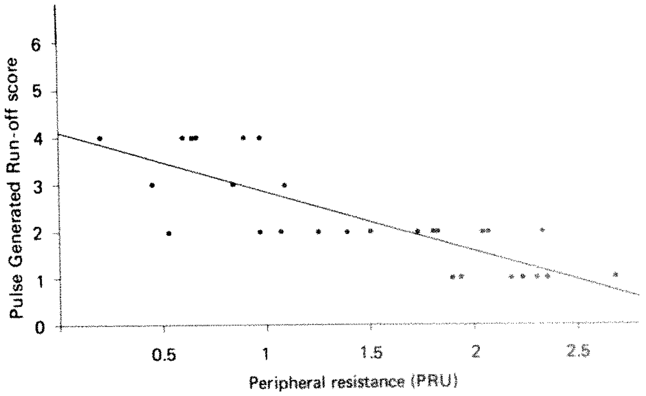

Figure 5 *Pulse Generated Run-off score* versus *the measured peripheral resistance in single calf vessel grafts* (n = *28*)*; PRU, peripheral resistance unit;* $r_S = -0{\cdot}82$*;* $P<0{\cdot}001$

views correlated better with the measured peripheral resistance than the scores from the conventional arteriograms (*Table 3*). In particular, scoring systems B and C correlated well with the measured peripheral resistance. In the 51 distal popliteal grafts there was reasonable correlation between the PGR and peripheral resistance ($r_S = -0{\cdot}36$, $P<0{\cdot}01$).

Distal calf (single calf vessel) reconstructions. Neither conventional nor intra-arterial DSA derived arteriogram scores A, B and C correlated with the measured peripheral resistance (*Table 4*). This probably reflects the limitation of arteriography particularly in patients with severe multisegment disease. There was excellent correlation between PGR and the measured peripheral resistance ((*Figure 5*) in the single calf vessel group ($r_S = -0{\cdot}82$, $P<0{\cdot}001$)

Discussion

Conventional arteriography has been the definitive investigation in patients with critical ischaemia and the decision to perform surgery is based on the visualization of an adequate run-off[17–19]. In patients with a single calf vessel, continuity with the pedal arch is a decisive factor in short- and long-term patency[5–7]. In the presence of multisegment disease and poor myocardial function visualization of calf vessel run-off and pedal arches using arteriography may prove impossible. The introduction of intra-arterial DSA has resulted in better vessel resolution with a lower contrast load but may not show very distal patent calf vessels.

Peripheral resistance has recently been shown to be of predictive value in the peroperative assessment of patients for femorodistal bypass but is an intraoperative technique and does not allow preoperative selection of patients[12–14].

In an attempt to improve the predictive value of arteriography various scoring systems have been devised, the simplest being graded 0–3, 1 point being given for each patent calf vessel[8–11]. LaMorte *et al.* found this simple scoring system to be of little predictive value in terms of the peripheral resistance measured at the time of surgery[10]. The poor correlation between the arteriogram score and the peripheral resistance was attributed to: (1) an inability of the scoring system to differentiate between good and bad vessels, and (2) an assumption that all three calf vessels contributed equally to the overall peripheral resistance. On the basis of these criticisms LaMorte devised a new scoring system which took into account the arch in the overall determination of peripheral resistance. This produced a better correlation with peripheral resistance, $r=0{\cdot}61$. One of the criticisms against the addition of an arch score is that some centres may not have the equipment, technical expertise or time to visualize these vessels.

In an attempt to standardize the use of arteriographic scoring systems in reporting run-off, the adhoc Committee (SVS and ISCVS) on reporting standards devised a novel method of assessing run-off[11]. The run-off was graded at the site of the proposed distal anastomosis. The grading system took into account the vessel chosen for the anastomosis, the severity of disease, patency of the arch if applicable and a base resistance. Peterkin *et al.* reported that the SVS/ISCVS scoring system correlated with the measured peripheral resistance ($r=0{\cdot}30$, $P<0{\cdot}01$), but was improved by weighting the individual calf vessel by means of multiple linear regression[20].

In this study three separate arteriogram scoring systems were correlated against the peripheral resistance. In the analysis of all 88 grafts there was poor correlation between the arteriogram scoring systems A, B and C and the peripheral resistance. In contrast, PGR correlated significantly with the measured peripheral resistance ($r_S = -0{\cdot}59$, $P<0{\cdot}001$).

The introduction of intra-arterial DSA produced an overall improvement in the correlation between the arteriogram scores and the peripheral resistance. In particular it improved the visualization of the proximal calf vessels and the subsequent correlation between the arteriogram scores and peripheral resistance. The better correlations with systems B and C probably reflect the superior methods of scoring. In system B the assessment was based over the first 5 cm of the calf vessel and in scoring system C the grading was based at the level of the distal anastomosis. Although system C is theoretically more attractive by basing the run-off at the level of the distal anastomosis, system B is much easier to apply and produces a similar correlation with peripheral resistance.

PGR correlates moderately well with peripheral resistance with an overall correlation for the 51 distal popliteal grafts of $r = -0{\cdot}36$. PGR in the present form does not assess the proximal calf vessels very well and this accounts for the poor correlation in the proximal grafts.

Table 4 *Spearman rank correlations between peripheral resistance, Pulse Generated Run-off and arteriographic scoring systems in reconstructions to single calf vessels*

Group	Correlation	Pulse Generated Run-off	Score		
			A	B	C
I (conventional angiography)	PR r_S	−0·80*	−0·2†	0·44†	−0·49†
II (intra-arterial DSA)	PR r_S	−0·86*	−0·39†	−0·38†	0·43†

DSA, digital subtraction angiography; PR, peripheral resistance; PGR, Pulse Generated Run-off; * $P < 0{\cdot}001$; † not significant

In the distal calf reconstructions the arteriogram scores derived from both the conventional and intra-arterial DSA films failed to correlate with the measured peripheral resistance. These results highlight some of the limitations of arteriography and the methods of scoring in patients with patent distal calf vessels not in continuity with the popliteal artery. By contrast PGR correlated extremely well with peripheral resistance in the single calf vessel group ($r_s = -0{\cdot}82$, $P < 0{\cdot}001$). This suggests that PGR is a superior test of calf vessel patency and should be used to select patients for distal reconstruction.

The use of intra-arterial DSA in combination with conventional arteriography has improved the visualization of calf vessels particularly in the proximal calf. The aggressive approach to the demonstration of these vessels must be balanced against problems related to increasing contrast dose. In most patients this is not a problem when using DSA but is when using conventional arteriography.

Arteriography gives anatomical information with limited functional data. PGR on the other hand provides the surgeon with a semiquantitative assessment of calf vessel run-off. It can also be used to map out the pedal arches and determine which calf vessels are in continuity with the arch. This is extremely helpful when planning surgery.

We conclude that selection of patients for proximal calf vessel reconstruction can be based on arteriogram scoring systems derived from intra-arterial DSA; PGR may help this level by showing continuity of calf vessels with the pedal arch.

Distal reconstruction should not be denied to patients who have no evidence of run-off on either conventional arteriography or intra-arterial DSA. PGR may identify patent distal calf vessels and determine their continuity with the pedal arches, both of which are essential prerequisites in successful femorodistal reconstruction. We feel that PGR is the method of choice for selecting the appropriate vessel for distal calf reconstruction.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Course in Clinical Surgery for The Final FRCS

Fee: £575

A full-time four-week Course in Clinical Surgery for the Final FRCS examination will be held at the Royal College of Surgeons from Saturday 3 – Saturday 31 March 1990.

The course will include clinical, practical and video sessions, pathology tutorials, day-release classes and a series of evening surgery lectures covering a wide range of relevant surgical topics. Residential accommodation is available.

This is the most comprehensive course in clinical surgery available, and applications must be received before the closing date of 1 December 1989.

Further details and application forms are obtainable from The Hunterian Institute Office, The Royal College of Surgeons of England, 35–43 Lincoln's Inn Fields, London WC2A 3PN.
Tel: 01-405 3474 Ext. 4107.

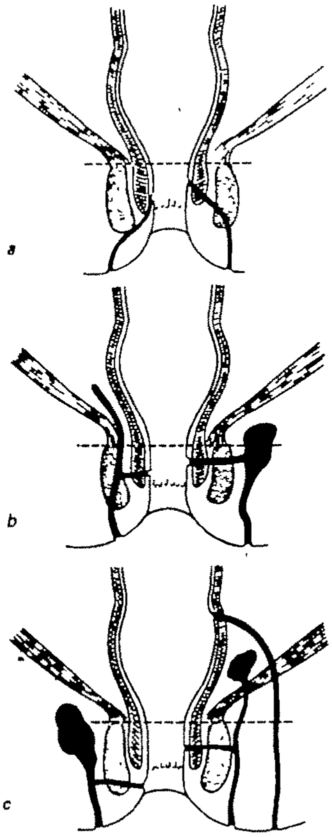
Essential Surgical Practice



★ Second edition of this classic systematic and comprehensive surgical textbook
★ Thoroughly revised and completely up-to-date ★ The section on cardiac surgery has been rewritten and to reflect its increasing importance there is a completely new section on trauma surgery ★ Over 100 new illustrations ★ Comprehensively indexed
★ Many references for further reading

Reviews

'What differentiates this textbook of surgery from many others is the clarity and simplicity of the text, the very liberal use of complementary tables, the illuminating simple diagrams, and the book's clinical relevance. The ease with which it may be read and the subject material understood makes this book a superior choice for students and residents interested in learning the essentials of surgical practice.'
The New England Journal of Medicine

'This book is highly readable and is a real contribution to surgical education.' *Archives of Surgery*

'It should be a great success on both sides of the Atlantic.' *Annals of the Royal College of Surgeons*

'... Covers very well an extensive range of material which is well illustrated and readily comprehensive. It should be very useful equipment for the trainee surgeon for the Australasian college.'
New Zealand Medical Journal

Management of hyperparathyroidism in pregnancy

J. S. K. Gelister, J. D. Sanderson, C. R. Chapple, J. L. H. O'Riordan, A. G. A. Cowie and E. J. G. Milroy

Departments of Medicine and Urology, University College and Middlesex Hospitals, London, UK

Correspondence to: Mr J. S K. Gelister, Department of Urology, Middlesex Hospital, Mortimer Street,
London W1N 8AA, UK

It has been suggested that all women diagnosed as hyperparathyroid during pregnancy should undergo neck exploration while pregnant to avoid the fetal and maternal hazards of hypercalcaemia[1,2]. Conservative management of women with mild hyperparathyroidism, reserving surgery during pregnancy for more severe cases, has been suggested as an alternative[3,4]. We report on 15 women in whom hyperparathyroidism was associated with pregnancy.

Patients and methods

Our cases were identified from a series of 1550 patients treated surgically for hyperparathyroidism.

In ten (Patients 1–10, *Table 1*) the diagnosis was made postpartum after the development of neonatal tetany. In one (No. 11) parathyroidectomy had been performed 3 years before her re-presentation with recurrent hypercalcaemia (serum calcium 3·5 mmol/l) in a pregnancy which resulted in a stillbirth and a postnatal pulmonary embolus. Subsequent neck and mediastinal re-exploration revealed parathyroid carcinoma.

Four patients were diagnosed during pregnancy and two of these underwent surgery during pregnancy. Of the two managed conservatively, one (No. 12) presented at 26 weeks with a pathological jaw fracture and underwent an otherwise unremarkable pregnancy. Thereafter a parathyroid adenoma was removed from her neck. Recurrent hypercalcaemia resolved after two further neck explorations. She re-presented pregnant and hypercalcaemic again. After an uneventful full-term delivery, parathyroid carcinoma was confirmed after a fourth exploration. The second patient (No. 13) presented with hypertension in the first trimester, hypercalcaemia being diagnosed midpregnancy. Following a Caesarean delivery for breech presentation the neonatal course was normal. A parathyroid adenoma was subsequently excised.

Both women explored during pregnancy presented with hyperemesis gravidarum. One patient (No. 14) presented at 6 weeks with a serum calcium of 3·4 mmol/l and a previous history of hyperemesis in pregnancy. Neck exploration in the first trimester of the second pregnancy revealed only four suppressed parathyroid glands, confirmed by histology. She was transferred with persistent hypercalcaemia and renal calculi were also diagnosed. The patient's symptoms settled and it was elected to defer further investigation and surgery until after delivery. The remainder of the pregnancy was unremarkable and the neonatal course normal. Subsequently a parathyroid adenoma was removed from the anterior mediastinum and percutaneous nephrolithotomy performed.

The last patient (No. 15) had severe hyperemesis, became dehydrated, developed renal failure, pneumonia and severe hypertension and became drowsy. She was then found to be severely hypercalcaemic (serum calcium 4·5 mmol/l) with elevated serum parathormone. At neck exploration four gland hyperplasia was discovered. Normocalcaemia was restored and the remainder of the pregnancy was unremarkable.

Discussion

In this series the commonest presentation was symptomatic neonatal hypocalcaemia. There were no maternal deaths but one stillbirth associated with severe hypercalcaemia and parathyroid carcinoma in a woman who had had a previous parathyroid exploration occurred. No asymptomatic patients were diagnosed during pregnancy by chance.

Since the introduction of multichannel biochemical autoanalysers up to 60 per cent of cases of hyperparathyroidism in general are diagnosed as a chance finding[5]. Surgical exploration is none the less recommended for these patients[6,7]. The

incidence of hyperparathyroidism in women of childbearing age suggests that the concurrence of this disease with pregnancy is more frequent than is indicated by the cases reported in the literature. The reasons for this discrepancy are that many asymptomatic cases remain undiagnosed as antenatal serum calcium estimation is not routinely performed and that uncomplicated cases are not reported. The suggestion that all pregnant woman with hyperparathyroidism should undergo surgery during pregnancy[1,2] is based, however, on earlier reports of conservatively managed cases noteworthy for complicated clinical courses. Thus Ludwig[8] reviewed 20 cases dating to the 1920s. Although he found a high incidence of obstetric complications many had florid hyperparathyroidism with serious complications. Furthermore, a relationship between these obstetric complications and hyperparathyroidism was not always obvious. Delmonico *et al.*[1] reviewed 14 further women managed conservatively and also noted a high incidence of neonatal tetany but only one neonatal death in a premature low birth weight baby whose mother had renal and bone complications.

During pregnancy there is transplacental passage of calcium ions but not parathormone from mother to fetus[9]. In hypercalcaemic mothers this is considered to lead to suppression of fetal parathyroid activity and such babies may develop tetany a few days after delivery. Transient neonatal tetany should not, however, be associated with long-term sequelae. Its occurrence in previous cases, usually the first sign of hyperparathyroidism in an otherwise unremarkable pregnancy, is not in itself a reason to advise neck exploration during pregnancy for all of these patients. In hyperparathyroid mothers neonatal hypocalcaemia is predictable and appropriate monitoring can be instituted.

In patients with severe or symptomatic hypercalcaemia, parathyroid exploration should be advised during pregnancy, the second trimester being suggested as the safest time[2]. In mild or asymptomatic cases it has been suggested that surgery can be safely deferred until after the pregnancy[3,4,10] and we agree with this policy.

The management of women with hyperparathyroidism during pregnancy requires a multidisciplinary approach preferably in a specialist centre[11]. If neck exploration is contemplated during pregnancy this clearly should be performed by an experienced parathyroid surgeon.

Influence of suture technique on surgical glove perforation

P. Chan and A. A. M. Lewis

Department of Surgery, Royal Free Hospital, Pond Street, London NW3 2PB, UK
Correspondence to: Mr A. A. M. Lewis

The prominence of diseases such as AIDS and hepatitis B has led to renewed interest in defining safe surgical techniques. Intact surgical gloves appear to be a barrier against human immunodeficiency virus[1,2] and recent studies suggest that glove perforation usually occurs during suturing, particularly laparotomy closure[3,4]. This trial investigates the contribution of active handling of the needle to glove perforation.

Patients and methods

From October 1987 to April 1988, 60 consecutive patients undergoing midline laparotomy were randomized to one of two methods of wound closure by random number allocation. All operations were performed by a single surgeon (P.C.). No patient was excluded

One closure method (A) restricted handling of the needle to the right hand by using a hand needle technique. The needle (Ethicon W711, 788, Ethicon Ltd, Edinburgh, UK) was both inserted and removed by the right hand. The left hand stabilized the wound but did not handle the needle.

The other closure method (B) restricted handling of the needle to the left hand by using an instrument technique. The right hand held a needle holder throughout, and was not exposed to sharp injury The left hand actively handled the needle (Ethicon W741, W786), removing it from the wound and remounting it

Gloves were changed before closing the wound and the new gloves were tested for pre-existing perforation. Wounds were then closed with a mass running suture of the abdominal wall layer, and interrupted simple sutures to skin. During wound closure, any overt glove puncture was noted and on completion of the operation the gloves were tested again and all perforations recorded. The gloves were then removed and the hands examined for evidence of injury.

Glove perforation was detected by an underwater immersion method The gloved hands were washed in sterile water for 60 s. Glove perforation allows water to be drawn in by capillary and osmotic action, passing through the starch powder within the glove This appearance is easily detectable by the naked eye.

Statistical analysis between the two methods of closure was made by non-parametric analysis (Mann–Whitney *U* test), or by the χ^2 test with Yates' correction as appropriate.

Results

There was no significant difference between the two groups in factors considered likely to influence the difficulty of wound closure (*Table 1*). Two gloves were found to be damaged when tested before wound closure.

There was no difference in the total number of perforations between the two methods, but all perforations occurred predominantly in the glove that actively handled the needle; the right glove in method A and the left glove in method B

($P<0{\cdot}005$, χ^2 test). Unrecognized perforations also occurred more often in the glove that actively handled the needle ($P<0{\cdot}005$, χ^2 test), and more perforations were unrecognized during method A, in which a hand needle was used ($P<0{\cdot}005$, χ^2 test), though this method was quicker ($P<0{\cdot}05$, Mann–Whitney U test; *Table 2*).

Discussion

Several methods of detecting glove perforations have previously been described The measurement of electrical permeability[5,6] may, in practice, be oversensitive, as it detects perforations too small to admit radiolabelled albumin, or even a methylene blue molecule[7]. Filling the discarded glove with water then examining for leakage[4,8] cannot exclude pre-existing defects. The immersion method used in this trial was first used in 1939 by Devenish and Miles[9] and is particularly suitable for detecting pre-existing perforation.

In this study, perforation occurred with a frequency comparable to those previously reported in the literature[2,3,5–9]. There were only two occasions in which skin injury occurred; 60 operations were performed. Although method A involved the use of a hand needle, as opposed to method B which used an instrument technique, both methods involved handling the needle and resulted in a similar number of perforations. The great majority of perforations (84 per cent), both recognized and unrecognized, occurred in the glove that actively handled the needle, irrespective of which method of wound closure was used.

Instrument techniques that involve active handling of needles are, therefore, no less likely to cause injury than hand needles. Active handling of needles should be avoided by a meticulous non-touch instrument technique. This will probably not eliminate glove perforation (both the glove exposed to passive injury in method A and that handling the needle holder in method B were punctured in this trial), but the risk will be much reduced

Prevention of recurrent saphenofemoral incompetence after surgery for varicose veins

G. M. Glass

Varicose Veins Clinic, Mater Infirmorum Hospital, Belfast BT14 6AB, UK

Correspondence to: Dr G. M. Glass, 22 Castle Street, Strangford, County Down BT30 7NF, UK

Recurrence of a varicose great saphenous vein, widely attributed to failure to ligate the vein proximal to all its tributaries, is frequently observed after an accurately performed saphenofemoral ligation. However, restoration of continuity of this vein after transection in the lower thigh[1], in the groin distal to tributaries[2,3] or at the saphenofemoral junction[2,3] may develop through neovascularization. A method of limiting the extent of such neovascularization at the saphenofemoral junction is described.

Patients and methods

Three methods were successively applied to three series of patients. From each series a group of patients that had been treated 4 or more years previously was reviewed. The methods and groups are described below

Group 1

In 141 limbs of 128 patients, saphenofemoral ligation with catgut, non-absorbable silk or tantalum wire was combined with multiple ligations.

Group 2

In 127 limbs of 109 patients, saphenofemoral ligation with catgut and closure of the opening in the cribriform fascia by suture was combined with multiple ligations.

Group 3

In 268 limbs of 152 patients, saphenofemoral ligation, with the application of a patch of synthetic mesh (Mersilene®, Ethicon Ltd, Edinburgh, UK) over the saphenofemoral junction and closure of the opening in the cribriform fascia, was combined with saphenous vein stripping. Use of mesh was introduced after recurrence caused by new vessels penetrating the fascia was observed in four limbs in group 2

Patients were reviewed after 4 years for evidence of recurrent saphenofemoral incompetence (return of symptoms, palpable varices in the groin, cough impulse, positive Trendelenburg test). In all cases of suspected recurrence the groin was explored for confirmation and treatment All procedures were performed by the same investigator. The χ^2 test was used to evaluate the data.

Table 1 *Incidence of recurrence of varices at the saphenofemoral junction after surgery*

Group	Mean (range) follow-up (years)	No. of limbs	No of limbs with recurrence
1	5·4 (4–8)	141	35 (25%)
2	4·9 (4–7)	127	4 (4%)
3	5·2 (4–6)	268	3 (1%)

Results

The incidence of recurrence was lower in both group 2 ($P < 0.001$) and group 3 ($P < 0.001$) than in group 1, and there was no statistically significant difference between the incidences of recurrence in groups 2 and 3 (*Table 1*). Where recurrence was noted in association with non-absorbable ligatures or mesh these materials were found incorporated in the new vessel. In one patient a sinus, which developed owing to infected mesh, was successfully treated by excision of the mesh.

Discussion

This investigation has shown a high incidence of recurrent varices at the site of saphenofemoral ligation. It has been reported previously that restoration of continuity at the site of transection of the varicose great saphenous vein may develop through newly formed vessels[1–4] and this is consistent with the present finding that construction of a barrier of cribriform fascia over the saphenofemoral junction significantly reduced the incidence of variceal recurrence. A defect of this method was occasional recurrence due to penetration of the fascia by newly formed vessels. While reinforcing the fascia with synthetic mesh may result in a further small reduction in recurrence of the varices, the incorporation of the mesh in newly formed veins and the possibility of sinus formation are disadvantages. Silicone rubber sheeting (Dow Corning Corporation, Michigan, USA) has been in use for several years and may be preferable to mesh.

The role of contrast radiography in presumed bowel obstruction

Fernando A. Riveron, MD, Farouck N. Obeid, MD, H. Mathilda Horst, MD, Victor J. Sorensen, MD, *and* **Brack A. Bivins, MD,** *Detroit, Mich*

A retrospective review of 229 patients with a final diagnosis of small-bowel obstruction was undertaken to evaluate the role of contrast radiography in the management of their conditions. In 84 patients (37%) the clinical findings and plain abdominal roentgenograms were sufficient for diagnosis and subsequent management. Of the remaining 145 patients with equivocal findings, 27% had an upper gastrointestinal series, 29% a barium enema, and 44% had both. Useful information (complete obstruction, unobstructed passage of contrast, or diagnosis other than adhesional obstruction) was obtained from 86% of the radiographic studies. Three patients had negative contrast studies yet eventually underwent adhesiolysis (enterolysis) and were classified as false-negative. Two patients had evidence of high-grade obstruction yet had nonoperative resolution and were classified as false-positive. The mortality in the contrast group (7%) was not statistically different than that in the no-contrast group (7%). Contrast radiography is a safe and effective means of increasing diagnostic accuracy in patients with presumed small-bowel obstruction. (SURGERY 1989;106:496-501)

From The Division of Trauma and Critical Care Surgery, Henry Ford Hospital, Detroit, Mich

OBSTRUCTION OF THE small intestine is one of the most common surgical emergencies and may constitute up to 20% of all urgent surgical admissions.[1] The accurate diagnosis of small-bowel obstruction and the indications for conservative versus operative management, however, remain enigmatic. Despite improvements from a mortality rate of 30% to 50% at the turn of the century to 5% to 6% in recent series, an estimated 9000 deaths occur annually in the United States as a result of small-bowel obstruction.[1,2]

Classically, the diagnosis of small-bowel obstruction is based on the clinical presentation: history, physical findings, and plain abdominal roentgenography. Although this is adequate for many patients, the physical findings and roentgenograms are often nonspecific. Differentiation between simple and strangulating obstruction, between partial and complete obstruction, and between mechanical obstruction and adynamic ileus is not always possible on clinical grounds. Sarr et al.[3] demonstrated that the preoperative judgment of strangulating obstruction by senior surgeons may be correct only 48% of the time. In 1961 Silen et al.[4] and in 1978 Stewardson et al.[5] found that the "classic" findings of leukocytosis, fever, tachycardia, and localized tenderness are often inadequate for the diagnosis of gangrenous bowel.

With the demonstration of the limits of clinical acumen has come an increase in the use of adjunctive diagnostic tests. The use of contrast radiography in the diagnosis of bowel obstruction has been variably regarded as superfluous to absolutely contraindicated. Yet the use of contrast radiography in the setting of acute bowel obstruction is being reported with increased frequency.[6-8] In a series by Dunn et al.[6] 21% of 327 patients with the initial diagnosis of small-bowel obstruction underwent contrast radiography, and useful information was obtained from 50% to 80% of these studies. In order to assess the role of contrast radiography in improving diagnostic sensitivity, we reviewed our experience from January 1982 to December 1985 in patients admitted with the presumed diagnosis of small-bowel obstruction.

MATERIAL AND METHODS

Three hundred patients coded by medical records with the admitting diagnosis of small-bowel obstruction were selected for study. Of these, 229 had a final diagnosis of small-bowel obstruction based on clinical

and roentgenologic criteria, operative findings, and hospital course. The remaining 71 patients were found to not have small-bowel obstruction on further investigation. The study group for analysis was limited to the 229 patients who had a final diagnosis of small-bowel obstruction. The criteria used for the clinical diagnosis of small-bowel obstruction included bloating, obstipation, vomiting, and a history of previous abdominal surgery. In addition, all of the 229 study patients had plain abdominal films consistent with small-bowel obstruction.

In the study group 84 (37%) of the 229 patients had clinical findings and plain abdominal roentgenograms sufficient for diagnosis and subsequent management. The case histories of the remaining 145 patients in whom contrast radiography was used to confirm the diagnosis were reviewed in detail. The diagnostic workup, timing, and use of contrast studies was variable and subject to the discretion of the particular attending surgeon; on review, however, it was apparent that contrast studies were used not only in cases of atypical presentation in order to define the disease, but also in patients for whom nonoperative management of their condition woud be particularly desirable.

By convention, patients with any possibility of colonic obstruction first underwent a barium enema with attempted reflux into the terminal ileum. If this was not diagnostic, an upper gastrointestinal series with small-bowel follow-through was performed. In general, contrast studies were obtained in patients with an atypical presentation or equivocal findings on plain abdominal films. Contrast was often used to define the degree of obstruction in patients in whom operative intervention was deemed particularly hazardous (for example, patients with Crohn's disease, short-gut syndrome, disseminated carcinomatosis, previous abdominal irradiation, early postoperative bowel obstruction, and multiply recurrent adhesional obstruction).

Table I. Radiologic findings of contrast studies performed on 145 patients

Radiologic findings	*No. patients*
No evidence of obstruction	77
Low-grade or moderate obstruction	21
High-grade or complete obstruction	22
Incarcerated ventral hernia	1
Crohn's disease	8
Carcinoma/radiation changes	16
Total	145

In order to determine the role of contrast radiography in the management of small-bowel obstruction, the study group was divided into three subgroups: primary adhesional obstruction, recurrent episodes of obstruction, and "other" causes—including early postoperative obstruction, obstruction from disseminated carcinoma, inflammatory bowel disease, previous abdominal irradiation, and hernias (Fig. 1).

The retrospective nature of this study limited our ability to analyze the impact of contrast studies on clinical decision making. Nevertheless, the specific roentgenologic findings and the radiologists' interpretation of the degree of obstruction were examined.

RESULTS

Of the 229 patients with a final diagnosis of small-bowel obstruction, there were 126 male and 103 female patients, ranging in age from 11 to 102 years (mean, 62 years). The majority of these patients (63%) underwent evaluation with contrast studies, whereas the remaining 84 (37%) patients were treated solely on the basis of the clinical examination and plain abdominal films. Of the 145 patients who underwent contrast radiography, 27% had a barium enema, 29% an upper GI series, and 44% both.

Adhesional obstruction was the predominant diagnosis in this study, accounting for 80% of the 229 patients with small-bowel obstruction. Other diagnoses seen in 20% of these patients included carcinomatous obstruction, previous abdominal irradiation, Crohn's disease, and hernias. In comparing the patients who underwent contrast radiography to those that did not, the first had a higher percentage of recurrent small-bowel obstruction and "other" diagnoses. Only 40% of the contrast group were primary adhesional obstruction; 39% were recurrent obstructions and 21% "other."

The specific information obtained from contrast studies varied according to the cause of the obstruction. The radiologic interpretation of the degree of obstruction was important in the decision to pursue operative versus nonoperative management. Similarly, the cause of obstruction was often delineated by the contrast studies. Information with therapeutic significance was derived from contrast studies, as summarized in Table I. These tests supported or confirmed the diagnosis of small-bowel obstruction in 86% of the patients studied. There were two false-positives (patients with high-grade obstruction who resolved spontaneously) and three false-negatives (patients with negative contrast studies who eventually came to adhesiolysis).

The finding that contrast passed without significant obstruction supported the decision to continue conservative management. Often, radiographic findings confirmed diagnoses that merited nonsurgical management (for example, Crohn's disease, disseminated carcinomatosis, or radiation enteritis). Conversely, an interpretation of high-grade or complete obstruction prompted early surgical intervention. Twenty-two patients had these ominous findings, 17 underwent adhesiolysis, and five were treated nonoperatively. Of these five, two refused surgery, and three were not considered surgical candidates by family and attending staff. Three of the five not operated on died, and two had spontaneous resolution of their obstruction.

There was no morbidity directly attributable to the use of contrast radiography in this study. There were, however, 11 deaths (7.6%) in the 145 patients undergoing contrast studies (Table II). This group had a mean age of 75 years. Two patients refused surgery. Six of the 11 patients had adhesional obstructions, four had nonresectable cancer (two had previously undergone abdominal irradiation), and one had small-bowel incarcerated in a large ventral hernia. Two of the deaths occurred after adhesiolysis. The operative findings in these two cases were closed loop obstruction in one patient and strangulating obstruction in the other. Both patients died of sepsis. The remaining patients were considered not to be surgical candidates because of their extreme morbid states. Comparatively there was a 6% mortality rate (5 of 84) among the patients treated without contrast studies (Table II).

Forty-five patients in the contrast group underwent surgical intervention. Of these, 17 were shown by contrast radiography to have high-grade or complete obstructions. Contrast studies were negative in three patients who eventually underwent adhesiolysis.

DISCUSSION

The traditional surgical dictum of early operative intervention for small-bowel obstruction has been

Table II. Mortality related to contrast study, operative intervention, and final diagnosis

Patient	*Age*	*Sex*	*Contrast study*	*Operation*	*Final diagnosis*	*Cause of death*

16	56	F	UGI/BE	No	Metastatic colon carcinoma	Pneumonia

tested as clinicians have sought ways to judge the safety of expectant management. In 1984 Brolin[7] demonstrated that 88% of patients with partial small-bowel obstruction have their conditions resolve in 48 hours with conservative management. Sarr et al.[3] have estimated the risk of conservative management of complete intestinal obstruction to be 31% ± 15%. The clinical quandary, therefore, lies in our ability to differentiate between partial and complete obstruction and in assessing the signs that herald bowel ischemia and dictate abandoning conservative therapy. In this study the admitting diagnosis of small-bowel obstruction was incorrect in 23.6% of patients. This is in concurrence with Silen et al.[4] who in a review of 480 cases of small-bowel obstruction found that 41% of patients with strangulating obstruction had only one or none of the classic signs of fever, leukocytosis, localized pain and absent bowel sounds. Fully 37% of their patients with gangrenous obstruction were admitted with a diagnosis other than bowel obstruction.[4] In examining these four classic signs, Stewardson et al.[5] defined the only statistically safe circumstance for "conservative observation" as the absence of all four classic findings. None of the 41 patients with absence of all four classic findings in our study had a gangrenous obstruction.

The plain abdominal film has long been a standard adjunct to clinical diagnosis of small-bowel obstruction. Brolin[7] found the initial set of plain abdominal roentgenograms to be the most reliable predictor of outcome. By the assumption that all patients with complete obstruction will require operation and those with partial obstruction will not, the radiologist's interpretation predicted the clinical course in 86%.[7] In distinguishing mechanical obstruction from reflex ileus, Lo et al.[8] estimated that abdominal x-ray films were accurate in only 60%. In 1943 Goldman[9] demonstrated that infarcted bowel loops are seldom seen on abdominal roentgenography because they rapidly fill with blood and fluid. He postulated that a normal roentgenogram in the presence of symptoms suggesting intestinal obstruction should always raise the question of strangulation.

Of the 229 patients with small-bowel obstruction in this study, 145 (63%) underwent an upper gastrointestinal series, barium enema, or both. Useful information was derived in 85.5% (definite diagnosis, no obstruction, high-grade or complete obstruction). Although there are obvious limitations in a retrospective study, clearly contrast radiography has become a frequent clinical adjunct in the treatment of patients with presumed small-bowel obstruction at our institution. Other authors have demonstrated the diagnostic utility of these studies as ranging from 50% to 75%. Dunn et al.[6] found that 68% of small-bowel studies gave useful information, whereas 75% of contrast enemas were helpful. Lo et al. derived what they considered pertinent information from 50% of contrast studies performed. Zer et al.[10] ascribed a reliability of 68% to meglumine diatrizoate (Gastrograffin) examination in correctly determining the need for operative intervention. In our study we had two false-positives and three false-negatives in 145 patients.

Opponents of the use of contrast studies in this setting cite potential catastrophic complications. The dangers associated with aqueous contrast media (Hypaque and Gastrograffin preparations, and metrizamide) relate primarily to their physical properties of hypertonicity and potential for precipitation.[11] These agents have a tonicity about six times greater than serum. Aspiration may cause florid pulmonary edema and reflex bronchospasm. There have been reports of precipitation of water-soluble contrast material by gastric hydrochloric acid yielding a "putty-like" mass in one patient's stomach and within the balloon of another's Sengstaken-Blakemore tube.[11] Hypovolemia may occur as a result of fluid being drawn into a contrast filled viscus because of the materials' hypertonicity. This may compound the dehydration exhibited by patients with intestinal obstruction. There has been at least one report of cecal perforation in a patient with an obstructing ascending colonic lesion who was studied with water-soluble contrast material.[11] Lo et al. and Miller in cumulative series found no complications in 329 upper gastrointestinal series performed for the diagnosis of small-bowel obstruction.[8, 12]

Similarly, there have been reported complications with the use of barium sulfate in the face of bowel obstruction.[11] The incidence of complications depends on the disease entity and may take the form of obstruction, perforation, impaction, aspiration, or embolization. In a murine model Berner and Johansen[13] demonstrated that peritonitis caused by a mixture of barium and feces is more lethal than that caused by feces or barium alone. Histologically, barium in the free peritoneum produces a severe granulomatous inflammatory response.[14, 15] Perforation of a peptic ulcer during roentgenography is a known complication. Small-bowel perforation has been reported in scleroderma and other connective tissue disorders. The reported incidence of perforation during a barium enema ranges from 1/2250 (0.04%) examinations to 1/12,000 (0.008%).[11] Barium impaction tends to occur proximal to obstructive lesions but is rare in the small bowel because of the fluidity of its contents. Prolonged stasis in the gut without obstruction may predispose to impaction. Barium appendicitis has been reported as early as the ninth day and as late as 105 days after a barium enema.[11] Aspiration of barium sulfate is generally well tolerated if in small volume. Barium embolization after an upper gastrointestinal evaluation is a rare event. Several cases of venous extravasation resulting in pulmonary embolization have been reported.[11]

In this series there were no complications directly attributable to contrast radiographic examinations. The overall mortality rate of 7% in this series compares with the 4.6% to 6.7% reported by others.[2, 5, 14] The aggressive use of contrast studies may be responsible for the low incidence of strangulation obstruction and the low mortality rate (6%) in this more critical subgroup. This compares with a published mortality rate of 4.5% to 50% in patients with gangrenous small-bowel obstruction.[4] On review it appears that the use of contrast radiography led to early appropriate operation in patients with operative lesions and encouraged appropriate nonoperative management in others.

On the basis of the data from this series and a review of the literature, select groups of patients who may benefit from contrast radiography may be defined. We propose the following indications for the use of contrast radiography in the setting of presumed small-bowel obstruction: (1) to clarify the diagnosis in patients with nondiagnostic abdominal films or an atypical clinical presentation; (2) to differentiate complete from partial obstruction on the assumption that complete or high-grade obstruction is less likely to resolve and more likely to progress to gangrene, (3) to differentiate paralytic ileus from mechanical obstruction; (4) to judge the relative safety of prolonged nonoperative management, particularly in subsets of patients in whom conservative therapy would be highly desirable—(a) patients with multiple previous celiotomies for adhesional obstruction, (b) patients with the differential diagnosis of early postoperative ileus versus obstruction, (c) patients who have undergone radiation therapy, (d) patients with disseminated carcinomatosis, and (e) patients in poor general medical condition in whom increased surgical risk argues against aggressive operative therapy.

At present, we believe that the patient with the classic findings consistent with strangulation or infarction caused by acute bowel obstruction should undergo early operation. In this we subscribe to the adage that "the sun should not set on a bowel obstruction." The clinical history, physical examination, and plain abdominal films remain adequate for the diagnosis of such a typical case of small-bowel obstruction. In patients for whom the diagnosis is equivocal the judicious use of contrast radiography may be of substantial benefit in charting a therapeutic course. Our findings indicate that contrast radiography should not be viewed as delaying operative intervention but should be employed early in the clinical course to help separate those patients who will benefit from early operation from those who can be successfully treated nonoperatively. The objective is early appropriate operative therapy combined with fewer operations for failure of conservative therapy. Our data support the utility of contrast radiography as a safe, effective means of increasing the clinical accuracy in the patient with presumed small-bowel obstruction.

Toxic megacolon and perforation caused by Shigella

Sir
We agree with the authors Gill, Feeley and Keane (*Br J Surg* 1989; 76. 796) that toxic megacolon with colonic perforation is not always due to inflammatory bowel disease but can occur in bacterial infections like *Salmonella* as illustrated by their case report. Colonic perforation in *Shigella* dysentery is rare and mainly confined to neonates[1] and infants[2]. Perforation in Bacillary dysentery in adults was reported in the Central American epidemic in 1969[3,4]. A recent case of perforation in a 73-year-old woman was reported by O'Connor and O'Callaghan[5] from Ireland. We would like to add our experience with a case of *Shigella* dysentery leading to toxic megacolon and perforation in an adult

A 68-year-old caucasian male, who had recently returned from India, presented with a 9-day history of diarrhoea with mucus but no blood, and griping abdominal pain. On admission he was dehydrated, pyrexial and had minimal abdominal tenderness in the right iliac fossa. Routine investigations were normal. A provisional diagnosis of gastroenteritis was made and he was treated conservatively Amoxycillin 500 mg three times daily was added after *Shigella flexneri* (2a) was isolated from the stool. Repeated blood cultures at various stages failed to grow any organisms. Amoxycillin was replaced by 960 mg co-trimoxazole twice daily after sensitivity results were known. After initial improvement he became unwell; plain abdominal and chest X-rays then showed free gas in the peritoneal cavity and a grossly dilated colon. A laparotomy showed friable and necrotic large bowel with perforations in three places. A subtotal colectomy (preserving the rectum) with ileostomy was carried out. Despite further intensive resuscitative measures, the patient died on the second postoperative day. The microscopic examination of the colectomy specimen showed widespread loss of mucosa replaced by very vascular granulation tissue with a thin covering of inflammatory exudate. The ulceration and subjacent inflammatory tissue extended into the bowel wall to various depths. No amoebae were identified. The slides were also reviewed for cytomegalovirus but no evidence of such infection was found.

The difficulty in distinguishing a patient with infective colitis from one with inflammatory bowel disease is well known and is described in the literature[6,7]. Inflammatory disease with concomitant bacterial infection does occur but recent studies[8,9] have shown that it is possible with reasonable certainty to distinguish inflammatory bowel disease from infective diarrhoeas on special histological features This should always be attempted if possible as preservation of rectum at the time of surgery is desirable in cases of infective aetiology.

War wound treatments

Sir
Coupland is correct in asserting that civilian surgeons with no war surgery experience can be taught to excise wounds[1]. However, excision of all war wounds, including the common punctate through-and-through rifle wound of the extremity with minimal tissue disruption and any wound seen several days after it was inflicted, imposes an unnecessary drain on surgical resources and inflicts a higher than needed complication and morbidity rate upon the patient. His *Figure 3* shows a 6-day-old wound being subjected to 'complete wound excision ' One must wonder at the blood loss from cutting across what must be highly inflamed tissues– this appears akin to excising, rather than simply draining, an abscess Apparently, the author of this paper was following recommendations from the International Committee of the Red Cross, recently published in *Surgery for Victims of War*[2] Underlying this guidance is the flawed concept that wound excision is the only acceptable treatment for all war wounds.

Friedrich originated the idea of excising the bacteria-laden area around the contaminated wound in 1898[3] He reasoned that, if the wound could be excised *within 6 hours* of the time it was inflicted, the bacteria would be removed (since they had not yet had time to invade), the wound could be closed primarily and heal without infection LeMaitre, in World War I, practised meticulous excision of carefully selected wounds, closed them primarily, and had a wound breakdown rate of only 2·36 per cent[4]. Both Friedrich, the originator of wound excision, and LeMaitre, its most successful practitioner, are quite clear in their application of wound excision only to wounds operated upon early after the wound was inflicted They both recommended only incision as needed (to assure relief of tissue tension and assure good drainage) and leaving the wound widely open in treating wounds seen a day or more after they were inflicted.

Odling-Smee[5], reporting on civilian casualties with war wounds, wrote: 'We also adopted the "wound trimming" technique described by Ogilvie[7] which consists of the removal of foreign matter and grossly lacerated tissues and the relief of tension throughout the wound, so that any accumulation in its deeper parts should more readily escape to the surface than along muscular planes. This procedure saved a great deal of time, and brought a result comparable with the classical debridement, where careful excision is required' Odling-Smee's findings are supported by recent experimental work[6]. Additionally, Ogilvie included as his first 'Cardinal sin' of war surgery[7]; 'unnecessary operations on through-and-through bullet wounds of soft parts.' He wrote that. 'The majority of these with rest and sulfonamide heal rapidly and leave no disability, operation means loss of time and loss of function '

Wound treatment recommendations in the recently revised *Emergency War Surgery – NATO Handbook*[8] contrast sharply with the advice given in the ICRC's *Surgery for Victims of War*[2] Recommendations reflected in the *NATO Handbook* are based upon recent experimental evidence[6] as well as a thorough review of historical war surgery experience.

The preponderance of available evidence would appear to indicate that the International Committee of the Red Cross is teaching their surgical recruits a method of wound treatment that is basically contraindicated for the great majority of the wounds they are called upon to treat

Abdominal radical total gastrectomy

Sir

The technique for abdominal radical total gastrectomy described by Chester and Gazet (*Br J Surg* 1989; **76**: 540) is not new. Immediate division of the oesophagus at the hiatus and the subsequent identification of the coeliac trunk was described by Roeder in 1933[1]. Roeder even suggested that the oesophagojejunostomy could be performed at this stage and the stomach removed 'at operation ten days later'.

We agree with Messrs Chester and Gazet that division of the oesophagus at the hiatus and development of the preaortic plane allows easy identification of the coeliac trunk and its branches, an essential step in radical gastric lymphadenectomy (R_3 resection). Whether this should be the first step in the operation is questionable. Conventional dissection[2] commences with omental detachment from the colon, followed by division of the gastroepiploic and right gastric vessels at their origin and then division of the duodenum. The spleen is reflected medially at a later stage in the procedure. Access is gained to the oesophagus from the left. This is divided and the coeliac trunk dissected as described by Chester and Gazet. This approach allows the more difficult retroperitoneal dissection to be performed later in the operation when mobilization of the stomach has improved the surgical access.

Colorectal cancer and cholecystectomy

Author's reply

Sir

We were disappointed to read Mr Bundred's letter (*Br J Surg* 1989; **76**. 1099) as it suggests he may not have appreciated the points we were trying to get across in our paper. We have stated quite clearly that the relationship between cholecystectomy and colorectal cancer remains controversial and that the overall risk (if real) probably would not justify a screening programme.

The suggestion that our literature review was highly selected is inaccurate. A comprehensive Medline literature search was carried out and all listed papers were included in the article With regard to the two papers mentioned by Mr Bundred, the first was not published when our paper was written and the second was not listed on Medline. However, even if they had been included they would not have made a significant contribution to the debate as they are both retrospective studies with the inevitable limitations. In our paper we have stated quite clearly that such studies will not help resolve this issue The argument will only be settled by properly designed prospective studies

Prader–Willi syndrome

Sir

Mr J.-J. Brossy advocates consideration of biliopancreatic bypass for all patients with Prader–Willi syndrome who survive to their teens (*Br J Surg* 1989; **76**: 313). He recommends this on the basis of an experience of one case. The case that inspired him to do this procedure was that of a 181 kg man with Prader–Willi syndrome who underwent jejunoileal bypass but who also suffered serious postoperative life threatening complications[1].

Mr Brossy has no grounds on which to recommend this operation in patients with Prader–Willi syndrome. Firstly, some of these patients are not obese or morbidly obese and many are not mentally retarded[2]. In a number of cases, obesity surgery is never indicated. Secondly many of the abnormalities in this syndrome, including temper tantrums and excessive daytime sleepiness, are not related to obesity and thus will not improve with weight loss[2]. Thirdly, nutritional deficiencies after biliopancreatic bypass are not uncommon as the author claims. Severe protein-calorie malnutrition is reported to be as high as 20–30 per cent and in some cases this has resulted in death. The statement that diarrhoea is seldom seen is also not true In the paper quoted it is stated that a patient with Prader–Willi syndome 'is such an aggressive consumer that the diarrhoea after intestinal bypass would probably be intolerable'[3]. Also in this paper the patients did not, as is stated, do poorly after gastric bypass. Six of seven patients with Prader–Willi syndrome lost weight and the authors comment 'that normal weight is seldom reached but that this is preferable to the risk of malnutrition'. Mr Brossy's patient was not morbidly obese, being only 34 kg over his maximum weight for height, and also did not attain normal weight losing only 20 kg which is a little over half of his excess weight.

In his operative description Mr Brossy fails to emphasize that the size of the gastric remnant is important as this has direct bearing on the amount of weight loss and the incidence of protein-calorie malnutrition It is important to understand the physiology of weight loss after this operation Scopinaro, its originator, quite clearly states that weight loss is due to the gastrectomy whereas later weight maintenance is controlled by the malabsorptive component.

Finally, 3-year follow-up is still very short and the importance of careful long term follow-up is not stressed and should be as many late complications after this procedure may develop. The recommendation that biliopancreatic bypass should be considered for all patients with Prader–Willi syndrome is unjustified, unsupported and dangerous.

Author's reply

Sir

I did not advocate that biliopancreatic bypass should be *done* in all cases with Prader–Willi syndrome; merely considered. Clearly each case must be assessed individually and those who are not obese or mentally retarded can be treated by other means. No surgeon sees more than a handful of these cases, so one is worth reporting In my experience of some 50 cases of biliopancreatic bypass (and a similar number of gastropexies) protein-calorie malnutrition has not been a problem; nor has diarrhoea. However 10–20 per cent of patients do get anaemia (iron deficiency due to jejunal exclusion) which can be very refractory to treatment. The size of the gastric pouch was not relevant to my report Finally, the follow-up is now nearly 5 years, and the proof of the pudding is in the eating – the patient remains well and the family is delighted with the result

Anatomical nit-picking?

Sir

Mr Scott is to be commended in his plea for a less nit-picking approach to teaching the surface markings of the deep inguinal ring (*Br J Surg* 1989, **76**: 206). It seemed to me when I was a medical student that the distinction between the midinguinal point and the midpoint of the inguinal ligament could be of little or no practical use and nothing has changed my mind since then. Mr Scott's last paragraph is entirely sensible and I hope it will comfort him to know that this is what we teach in the Royal College of Surgeons in Ireland to undergraduates and postgraduates. Students are failed no longer as a result of confusing the midinguinal point with the midpoint of the inguinal ligament

Mr Scott's pragmatic approach to the inguinal region could be taken further. Whatever the textbooks may say about the surface marking of the superficial inguinal ring, it is rarely found medial to the pubic tubercle, as even a cursory study of patients and anatomical specimens shows. The only constant feature about it is that it is superior to the pubic tubercle. Neither does the spermatic cord often pass medial to the pubic tubercle: we have several specimens in which it either overlies, or is quite markedly lateral to, the pubic tubercle as it descends into the scrotum. Anatomy does not need to be made unnecessarily complex by mystical beliefs such as these handed down from book to book and generation to generation.

Anorectal function after abdominal rectopexy

Sir

We read with interest the paper by Yoshioka *et al.* (*Br J Surg* 1989, **76**: 64–8) on anorectal function after abdominal rectopexy and would like to concur with their findings.

In a prospective study of 6 incontinent patients with rectal prolapse studied manometrically before and after abdominal rectopexy, we have found that there is no statistically significant change in resting anal pressure after operation. Furthermore, the majority of patients obtained a marked improvement in anal continence despite a significant reduction in rectal capacity.

Our results and those of Yoshioka *et al.* would suggest that recovery of internal anal sphincter tone, as suggested by Broden *et al.*, is not the reason why continence improves after rectopexy[1]. We feel that abdominal rectopexy is a safe method for treating patients with full thickness rectal prolapse which has a low recurrence rate and provides good clinical results. The improvement in anal continence is probably related to a number of factors; we suggest that the constipation frequently encountered in patients after rectopexy plays a major role in this aspect of the functional outcome.

Diseases of the Arterial Wall

J P Camilleri, C L. Berry, J N. Fiessinger and J. Bariéty
275 × 195 mm. Pp. 693. Illustrated. 1989 London. Springer-Verlag. £216 50.

The editors and authors of this excellent textbook all work in French-speaking Europe or the UK and they are to be congratulated on a *tour de force*. This beautifully produced book covers every possible aspect of the biology and pathology of the arterial wall. It is expertly translated from (I presume) its original French, it is well documented and illustrated and it contains a most comprehensive bibliography· one chapter of 17 pages has 459 references. The references are culled not only from the conventional North American and UK literature, but also from European journals and therefore reflect the full field of published research.

This is not a book that many individual clinicians would wish to have on their shelves, but it is essential to any first class library. It fills an important gap in our understanding of the pathology of vascular disease and must represent the most up-to-date and comprehensive work on the subject. The editors and authors are to be congratulated on their gigantic effort, which has been rewarded by such a comprehensive and interesting volume

Surgery of the Oesophagus

G. G. Jamieson. 216 × 279 mm Pp. 911. Illustrated. 1988 London Churchill Livingstone. £135 00.

The concept of oesophageal surgery becoming a specialty in its own right was perceived by R. H. Franklin when he published his classic monograph entitled *Surgery of the Oesophagus* almost 40 years ago However, few would have predicted the enormous growth of interest in oesophageal surgery and the considerable developments which have resulted in the need for this very large volume with over 100 contributors.

The book characteristically begins with sections on anatomy, physiology and investigation of the oesophagus. However, what distinguishes this volume from its competitors is the depth of detail in its coverage of the surgical management of oesophageal disease in children and adults, and particularly the comprehensive detail of operative techniques contained within its 105 chapters. In addition to the various surgical approaches to the management of such conditions as gastro-oesophageal reflux, benign structure and oesophageal carcinoma (each being discussed by an expert in that approach), there is a very useful and well illustrated section towards the end of the book on 'Techniques in Oesophageal Surgery'. Also of value is the section on management of the complications of oesophageal surgery, serving to remind us that the oesophagus is an unforgiving organ

The book is impressive in its coverage and has been well produced. Criticisms are relatively few and relate to the problems of producing such a large multiauthor volume. There is inevitable overlap in some areas and relative inequality in the degree of detail assigned to various topics, with 11 pages on Chagas' disease and a mere half page on 24-h pH monitoring. Despite the extensive detail by many authorities on the various types of antireflux surgery, it is disappointing to see so few objective data to enable the reader to make any informed choice. There is a paucity of references within the last 5 years, during which time many significant advances have been made.

Professor Jamieson has produced an authoritative and comprehensive volume which will be a useful work of reference for those surgeons who have a significant involvement with patients with oesophageal disease.

Advances in Surgery, Volume 22

Tompkins, Balch, Cameron et al. 230 × 160 mm
Pp. 334. Illustrated. 1989. Chicago· Year Book Medical Publishers Inc. £39 50.

Most of the 11 chapters in this volume are good value. The management of liver secondaries receives a 'full-frontal' approach, but lingering doubts are nevertheless properly addressed. The obligatory chapter on AIDS is well balanced. However, the article on blood transfusion is outstanding and spells out the known as well as the potential dangers of blood products This should be required reading for anaesthetists as well as surgeons, for we should no longer accept one-unit transfusion (even if this is often increased to two units to make it look respectable), but should avoid transfusion if at all possible. There is one chapter on splenectomy for haematological disease and another on surgical aspects of lymphoma which has inevitably led to much duplication, yet mention of overwhelming post-splenectomy sepsis is confined to the references and its prophylaxis is not discussed.

The authors of the chapter on occult gastrointestinal bleeding are able to rely on arteriography for both diagnosis and treatment to an extent that is not readily available in many centres. Carcinoma of the thyroid, hepatic trauma and heart–lung transplantation are fully discussed with a sensible analysis of the controversial issues. The discrepancy in carotid endarterectomy rates between the US and the UK is enormous, but the chapter on the indications of this operation concludes that there is still a lack of adequate data Advances will come from prospective studies of medical *versus* surgical treatment, but there is no mention of a randomized trial and perhaps this is no longer possible. The discrepancy in the usage rates of Greenfield filters must be even greater than that for carotid endarterectomy and it is a pity that this issue is not given an airing

Molecular and Cellular Mechanisms of Septic Shock

B. L Roth, T. B Nielsen and A E. McKee 155 × 235 mm. Pp. 330. Illustrated. 1989. New York Alan Liss Inc. $58.00

Like many in the series, this book is a report on the proceedings of a conference which was held in Bethesda, Maryland, in March 1988 Rapid publication has been achieved at the expense of the use of variable typefaces. All of the papers contained within the book come from American centres with 60 per cent of all authors from Bethesda The book provides an excellent update into certain aspects of current research into the pathophysiology of septic shock There is an excellent index which is commendable given that it represents the proceedings of a meeting. The papers are divided into three sections. The first deals with cellular receptors and signal transduction, in particular the recent implication of phospholipase C coupled receptors in the pathophysiology of sepsis and endotoxaemia. The second section reviews the role of endotoxin as a mediator of septic shock. This section contains a number of interesting papers, including a review of the role of lipid A analogues in the treatment of septic shock and the description of a rapid, though non-quantitative, assay for the detection of endotoxin in plasma. The final section deals with the role of cytokines in the metabolic pathophysiology of sepsis. This includes an excellent review on the effect of monokines on hepatic metabolism, including evidence for a two-way cell–cell signalling between Küpffer cells and hepatocytes.

In summary, the text provides an excellent in-depth review of certain aspects of the pathophysiology of septic shock It is perhaps surprising that little mention was made, in the endotoxin section, of the gastrointestinal tract as a source of endotoxin. The book contains little of direct clinical relevance to the practising surgeon, but will undoubtedly appeal to individuals working in the field of septic shock research, regardless of their background specialty.

Acupuncture, Trigger Points and Musculoskeletal Pain

P E Baldry. 250 × 195 mm. Pp 308. Illustrated. 1989. Edinburgh: Churchill Livingstone £27.50.

This book sets out to summarize the history of acupuncture and to review critically several fairly recent studies which attempt to provide a scientific basis for some of the reported phenomena. This makes quite interesting reading for surgeons, especially since the myth of acupuncture anaesthesia is exposed. However, the remaining two-thirds of the volume is a recipe book, describing certain 'trigger points' which, when stimulated by the insertion of a 'dry needle', may relieve pains of musculoskeletal origin. The 'value' of this procedure is illustrated by numerous anecdotal accounts of success but it contains no instructions for relieving the sorts of pain commonly encountered in surgical practice

In summary, an interesting book to browse through while dozing in a deckchair on a warm summer afternoon, but not to be taken too seriously unless a visit to mainland China is imminent

Pancreatic Transplantation

C-G Groth. 160 × 235 mm. Pp. 413. Illustrated 1988. Philadelphia: W. B. Saunders Company. £50.00.

This multiauthored book contains 27 chapters and is edited by a major contributor to the field. There is as yet no standard surgical procedure for pancreatic transplantation, nor is it known whether transplantation of the islets alone is sufficient. The imprecise state of knowledge is reflected in a critical chapter by the Editor which attempts to evaluate the various ways of dealing with the technical problems; for instance, should the duct be occluded by polymer or should it be drained? If so, should it be drained into the peritoneal cavity (surprisingly, this was shown to be possible), into the gut or into the bladder? Some trends can be discerned: for example, the enthusiasm for ductal occlusion has declined Diversion to the urinary tract is attracting considerable interest as it is technically easier, and analysis of the urine can warn of a reduction in exocrine secretion and the onset of rejection.

Early pancreatic transplants were performed in a similar manner to renal transplants by anastomosing the vessels to the iliac system. As a consequence, insulin is directed into the systemic rather than the portal circulation. However, using a variety of procedures, the venous effluent from a pancreatic graft can be made to drain into the portal venous system. As yet there is no clear metabolic advantage for choosing this more difficult surgical option. The perioperative and postoperative management is well documented, and postoperative complications are given special mention in separate chapters

Whether the pancreas is more or less prone to graft rejection than other organs has always been speculative. In fact, rejection is not necessarily the predominant cause of graft failure, as early technical failures are the main problem. The main thrust of work on the control of immunosuppression is now directed to the early detection of the rejection process by looking at the exocrine function which seems to be affected earlier than the endocrine function.

It is only now that there are sufficient numbers of patients surviving to determine whether there is a reduction of the pathological changes arising from the diabetic state. It is not yet possible to see whether the denervated pancreatic graft functions as well, nor whether the commonly associated renal failure adversely affects pancreatic graft function. There is a suggestion that in some patients there is a recurrent process in the graft which is similar to that producing the initial diabetic state.

There are so many unknown factors in pancreatic transplantation that we can only begin to appreciate the complexity of this promising organ transplant. Perhaps a further edition of the book will be required in a relatively short time and by then we may begin to see whether transplantation of the islets will be a better option, for there is perhaps too little emphasis on this aspect in this book.

It is, however, an excellent review of this expanding area of transplant surgery and can be warmly recommended

Perspectives in Vascular Surgery

J. Goldstone. 260 × 180 mm. Pp 162. Illustrated. 1988. St Louis: Quality Medical Publishing Inc $165.00 (US)

This is a new and unique type of surgical publication which tries to fill the gap between the scientific research of the learned journal and the overview of the surgical textbook, which can too often be dated by the time of publication. This book is a multiple author work and, like a journal, is up to date, being published in 1988 and containing references from the same year. Like a textbook, overviews of selected topics are presented with an in-depth bibliography and the result is a work containing much clinically and scientifically useful information. An unusual feature is the deliberate variation of the layout of the articles, which include discussions of clinical topics with final comments by an Editor, descriptive articles on technique, editorial opinion on clinical problems presented by contributors, and discussions between experts on current controversies. The topics covered include lasers, concurrent aneurysm and coronary disease, reversed *versus in-situ* vein grafts, venous reconstruction, visceral ischaemia and asymptomatic carotid stenosis. With an almost all-American Editorial Board and list of contributors, it is not surprising that there is a trans-Atlantic slant to much of the opinion. Perhaps this makes it less a volume for the surgeon in training than for the established vascular surgeon. This book is Volume 1, Number 1 of a series to be published twice-yearly and is available only by subscription. It is not a book for personal purchase, although some vascular units will find it interesting to have on their library shelves.

Clio Chirurgica Liver Transplantation

T. Starzl, C.-G. Groth and L Makowka. 280 × 215 mm. Pp. 363. Illustrated. 1988. Texas. Silvergirl Inc

This volume of *Clio Chirurgica* is a compendium of papers relating to the development of experimental and clinical liver transplantation over the last 30 years.

The development of liver grafting has been achieved only after years of dedicated laboratory work into the pathogenesis of rejection, the development of chemical immunosuppression, improvements in liver preservation and the many major technical problems involved. The historical papers which chartered this course are drawn together here in one paperback journal and the backgrounds to the important developments are briefly outlined. With so much work in the field and so many contributors, inevitably criticisms will be made of the inclusion of some and the omission of others Perhaps surprisingly, scant documentation covers the introduction of cyclosporin, something which has done so much to revolutionize immunosuppression in liver transplantation and the care of these critically ill individuals. Also, the contributions of the hepatologists, gastroenterologists and pathologists who play such a role in modern liver transplantation are not highlighted in the paper selection.

The presentation suffers significantly because so many of the papers included contain a high proportion of line drawings, diagrams and histological illustrations. Many of these reproduce poorly, are indistinct and some are frankly undecipherable. Clearly readers will need to turn to the original articles for a proper perspective; indeed, what appears here is a linking together of photocopied papers with comments, and this is perhaps disappointing given the importance and momentous changes outlined within these papers.

This compendium has its rightful place in a series devoted to collecting pioneering papers in the field of surgery, although it is likely to be of most interest to those relatively limited number of clinicians working actively in the field at this time. It is perhaps unusual, in a collection of pioneering papers, to find that the majority of authors are currently alive, and many of them are still active in the field. However, many such individuals, particularly the Europeans, may look in vain for their own contributions in this selected compendium!

Operating Theatre Technique

R. J. Brigden. 250 × 295 mm. Pp. 968. Illustrated. 1989. Edinburgh. Churchill Livingstone. £65.00

Brigden's Operating Theatre Technique has earned the deserved place of being the standard reference text for all theatre users, theatre managers and theatre designers. Since the first edition in 1962, successive generations of theatre personnel have relied upon the information, the definition of principles, and the explanation of controversial matters contained within its pages. The fifth edition maintains previous high standards in accuracy of information, in the comprehensive coverage of the subject matter, and in the provision of clear diagrams and illustrations. The first chapter on operating department design has been revised and extended. This rightly takes into account the change in the advisory machinery through which planning processes channel medical and nursing information into project development, and highlights the change in opinion about the microbiological basis for the old tradition of clean and dirty zones The chapter on electromedical equipment, which now includes information on lasers, cryoprobes and ultrasonic apparatus, brings together information which is difficult to gather from other more specialist sources and puts it in a way that is comprehensible to theatre users It has previously been rather difficult to reproduce good colour pictures of the view seen through endoscopes or operating microscopes, but the illustrations in this edition are particularly good in this respect.

The reputation of this reference work is now so considerable that there is a danger than the information presented will be regarded as incontrovertible; where such an inexact science as medicine is concerned contrary views are always possible. Nevertheless, a balance has been struck with the benefit of 26 years of experience. The result has been that an excellent fourth edition, produced in 1980, has been succeeded by an even better fifth edition which will find its place in operating theatre suites, in teaching schools, and in the libraries of serious theatre users of every grade.

Anorectal Malformations in Children: Update 1988

F. Douglas Stephens, E Durham Smith and N Paul. 230 × 155 mm. Pp. 620. Illustrated. 1988. New York. Alan Liss Inc $150.00.

In this tome, the Editors are assisted by 13 contributors of international repute, each having made important advances in the treatment of infants with anorectal malformations.

The clinical photographs are good, but those of operative procedures serve no useful purpose. Some of the illustrations are so small that they are difficult to understand The reproduction of radiographs is adequate, but it is confusing to have diagrams of operations interspersed in the text describing different procedures. Two classifications of the more common anomalies are offered; a third is then offered for rarer lesions which does not fit into either class!

Relatively few pages, about 3 per cent, are devoted to somewhat optimistic short-term results, and the problems of the incontinent teenager are barely mentioned. I was astounded to see paediatric surgeons recommending the use of suppositories and petroleum emulsion for constipated children. Ultrasonography of the perineum is discussed, but not illustrated, and although pelvic CT scans are said to be of increasing importance, only nine badly reproduced 'cuts' demonstrate the point.

The book suffers from the problems associated with multiauthorship There is repetition from one chapter to another, with some contributors offering conflicting advice. Some operations are described in varying ways by different contributors. The book would have benefitted from judicious editing, which could have reduced its length by at least a third

As a reference work, the book is unique. The comprehensive list of references, from 1543 to 1987 inclusive, is of value in itself but in an 'update' I had not expected to find 'Reproduced with permission of the publishers' on over a third of the pages. Perhaps 'all that there is' has been included, but I had expected more

Reconstructive Microsurgery

B McC. O'Brien and W. A. Morrison. 285 × 225 mm. Pp. 540. Illustrated. 1987. Edinburgh: Churchill Livingstone. £120.00.

The senior author, Mr Bernard McC O'Brien, is internationally respected as the father of modern microvascular surgical techniques. He has for many years been ably supported by Wayne Morrison who, similarly, is known for his original contributions to this specialty. At the Microsurgical Research Centre in Melbourne, surgeons from all over the world have learnt the basic techniques of microvascular surgery, and how to apply them in the transfer of skin, muscle, bone, nerve, tendons and many other tissues. The first book by Mr O'Brien, *Microvascular Reconstructive Surgery*, was published in 1977 and had only one chapter devoted to free flap surgery. Over the last 12 years, an explosion in this form of transfers has occurred and the new book requires some 20 chapters to cover the subject. The unit in Melbourne has been the forerunner of placing microvascular and microneural repairs on to a proper scientific basis. They have explored many methods of transferring tissues, and have examined the pathological results. Many of the techniques have already been described in the journals, either published by themselves or by others. Clearly the authors have tried these various procedures and are in a good position to describe the advantages and pitfalls of them.

Reconstructive microsurgery is a fascinating field which is constantly developing and therefore any book like this is unlikely to be absolutely up to date. The presentation of the work is clear and concise, with intelligent use of illustrations The reference literature is meticulous and particularly helpful, as the bibliography pertaining to this subject is widespread, only recently having an international journal of its own. The particular strength of the book is that it is the experience of a single unit following the growth of a specialty from its earliest development to the present time. It does not rely on multiple authors and is therefore much less uneven and more readable. It is really the best publication of its type and is essential for any surgeon interested in this field of surgery. It will form an excellent basis for the next development in this field, which must be the transplantation of these tissues to another individual.

Atlas of Advanced Surgery

M. S. Litwin 310 × 235 mm. Pp 198. Illustrated. 1986. London Yorke Medical Books £60.00.

For the general surgeon interested in gastroenterology, this slim 200-page volume neatly fills the gap between publications devoted to basic techniques of standard operations and the multivolumed works covering all the specialties. The Editor has chosen a team of authors, each of whom is an expert in his field, who have either designed or perfected the operation they describe, but a firm editorial hand has maintained a uniformity of style throughout. The emphasis is on clear illustrations of operative procedures and the text has been kept to a minimum, assuming a basic knowledge on the part of the reader. Most of the more major and complicated procedures in gastrointestinal surgery are described, but there are one or two surprising omissions in oesophageal and colorectal surgery. For example, although replacement of the oesophagus with colon is described, three-stage oesophagectomy with gastric reconstruction is not included. Only one form of ileal pouch–anal anastomosis is described. A minor irritation is the tendency to use eponymous titles for instruments instead of a functional description. In a few instances pyloroplasty is illustrated in a misleading way, although, in general, the illustrations are excellent. In the description of low anterior resection, taking down the splenic flexure is felt to be only occasionally necessary; many surgeons would disagree with this and would regard it as an important step in the procedure However, these are minor criticisms and this book succeeds admirably in its purpose I recommend it to all general surgeons with an interest in gastroenterology.

Surgery for General Practitioners

B. Maurice. 220 × 140 mm. Pp. 264. Illustrated. 1989. London: Castle House Publications Ltd. £15.00.

Brian Maurice has written a book based on lectures given to general practitioners. It behoves all general surgeons to be aware of this book in the light of current proposals to improve services to patients. There are a number of good arguments both for and against general practitioners performing certain minor operative procedures in their surgery. Given motivation and appropriate training, however, there are certain socioeconomic advantages to one or two general practitioners in large group practices undertaking a central role in the performance of specific operations.

The author makes the point that 'there is no place for a general practitioner to do the occasional minor operation', and clearly and concisely explains everything that a dedicated general practitioner needs to know to perform more than 20 operations under local anaesthetic in their own surgery. He has enlisted the help of a consultant anaesthetist who covers the subject of local anaesthesia, with or without sedation; maximum recommended dosages for three common agents are given. Early treatment for problems is emphasized and the reader is told, in no uncertain terms, that facilities to deal with circulatory arrest must be readily available.

The book is full of sound advice and warnings of the pitfalls to be avoided, reflecting the general surgical experience of the author. Criticisms that I made while reading this pithy volume were, on reflection, subjective and based on anecdotal experience.

The chapters on instrumentation, suture materials and stitching are easy to follow, and I would recommend them for any doctor in training who is involved in performing minor surgery. Even those general practitioners who elect to refer their patients to hospital would benefit from reading the chapters on specific operations and treatment of postoperative complications.

In these days of increasing specialization and controversial White Paper proposals, this book fills an important niche and is welcomed unreservedly.

Clinical Thinking in Surgery

E A. Sterns. 180 × 260 mm. Pp 642. Illustrated. 1988 East Norwalk: Appleton and Lange. £24 50.

This is a most welcome and interesting addition to the large number of available textbooks of surgery. It is intended for the medical student and aims to set out the relationship between the basic sciences (particularly of anatomy, physiology and pathology) and clinical thinking It emphasizes the basic science and then presents clinical material in the form of illustrated cases that represent common clinical situations. The author aims at a coverage comprehensive enough for the needs of the average medical student, but which is limited to the entities that are both common and particularly valuable in illustrating the logic of treatment

After a chapter on approaches to the solution of surgical problems, the material is arranged in four sections· the first covers general problems such as wound healing, infection and shock, the second is a very comprehensive section on regional problems; the third section is about trauma and burns; and the fourth section discusses preoperative and postoperative care.

The style is attractive, being readable and enjoyable, crisp and clear, and at times challenging and exciting. The illustrations, mainly line drawings, are clear although many are not original. There is an appendix which discusses how to conduct a literature search and this is indeed a welcome feature The format is attractive with double columns and, while it will not fit into a white coat pocket, it is a very manageable paper-covered volume. British medical students will, I believe, find it more to their taste than most of its trans-Atlantic rivals.

A Colour Atlas of Human Dissection

C. C Chumbley and R. T. Hutchings. 100 × 120 mm Pp 160 Illustrated. 1988. London· Wolfe Medical Publications. £14.95.

This book offers 'a scheme of practical anatomy' It is lavishly illustrated, hence the title, and the photography is excellent. Dissection instructions are brief and it is suggested that they be used in tandem with another colour atlas: page and *Figure* references to the McMinn and Hutchings atlas are cited. It is evidently intended in the first place for students beginning their anatomy course rather than postgraduates, e.g those students studying for the FRCS primary examination.

I think that junior students will have difficulties with this book (postgraduates to a lesser extent). First, they are committed to the extra expense of buying another atlas. If the photographs in the present atlas had been labelled, it would have been cheaper for the student.

Second, the order of dissection (some surface anatomy and osteology are included) of parts starts with the most difficult region: head and neck, upper limb, thorax, abdomen and pelvis, and upper limb. However, the teachers may elect to start where they wish

Third, there are the usual problems where a brief simple approach is attempted. Thus there may not be enough information for the inexperienced student to locate and identify the structure he is ordered to find. In some photographs a structure is clearly indicated by, for example, forceps, but there are several examples (mostly 'close-ups') where even the experienced eye would have difficulty in orientating the picture relative to the body, let alone identifying the required structure. In addition, the brief format seems to me to induce a divorce between structure and function. Surely there are no better places than in the dissecting room and in a dissecting manual to explain function. What would be the point of painstakingly dissecting the origins and insertion of the sternocleidomastoid muscle and the course of the spinal accessory nerve if the student is not told or asked to deduce what the muscle does and that this nerve supplies it?

I believe that some modifications are required to make a second edition more useful to the student. The publishers are, however, to be congratulated on a technically well produced book.

SCIENTIFIC PAPERS

288 **Flow Cytometric DNA Analysis of Primary and Concurrent Metastatic Squamous Cell Carcinoma of the Head and Neck**
Julian A. Kim, Valerie L. Moore, Mukund S. Didolkar, Jose V. Ordonez, Robert A. Van Wesep, and Charles M. Suter

292 **Surgical Management of Squamous Cell Carcinoma of the Floor of the Mouth**
Richard W. Nason, Kumao Sako, Wayne A. Beecroft, Mohamed S. Razack, Vahram Y. Bakamjian, and Donald P. Shedd

297 **Oncologic and Functional Considerations of Total Glossectomy**
Mark R. Sultan and John J. Coleman III

303 **Thirty-Year Experience With 457 Radical Neck Dissections in Cancer of the Mouth, Pharynx, and Larynx**
René A. Khafif, Gary A. Gelbfish, Joseph N. Attie, Patrick Tepper, and Robert Zingale

308 **Editorial Comment**
Mukund S. Didolkar

309 **Elective Versus Therapeutic Neck Dissection in Early Carcinoma of the Oral Tongue**
Abdul R. Fakih, Raja S. Rao, Anita M. Borges, and Ashraf R. Patel

314 **Prognostic Factors in Squamous Cell Carcinoma of the Larynx**
Jason D. Eiband, E. George Elias, Charles M. Suter, William C. Gray, and Mukund S. Didolkar

318 **Management of Advanced Glottic Carcinomas**
Mohamed S. Razack, Tanaphon Maipang, Kumao Sako, Vahram Bakamjian, and Donald P. Shedd

321 **Speaking Jejunum After Laryngopharyngectomy With Neoglottic and Neopharyngeal Reconstruction**
Manfred Ziesmann, Brian Boyd, Ralph T. Manktelow, and Irving B. Rosen

324 **Efficacy of an Antibiotic Mouthwash in Contaminated Head and Neck Surgery**
Timothy R. Jones, Helen Kaulbach, Larry Nichter, Richard F. Edlich, and Robert W. Cantrell

328 **Squamous Carcinoma of the Nasal Cavity and Paranasal Sinuses**
Jeffrey D. Spiro, Kee Chee Soo, and Ronald H. Spiro

333 **Reconstruction With Free Bowel Autografts After Pharyngoesophageal or Laryngopharyngoesophageal Resection**
Michael B. Flynn, Joseph Banis, and Robert Acland

337 **Microvascular Approach to Function and Appearance of Large Orbital Maxillary Defects**
John J. Coleman III

342 **Fine-Needle Aspiration of Parotid Tumors**
Hector P. Rodriguez, Carl E. Silver, Idel I. Moisa, and Mary S. Chacho

345 **Reversal of Impaired Wound Healing in Irradiated Rats by Platelet-Derived Growth Factor-BB**
Thomas A. Mustoe, James Purdy, Peggy Gramates, Thomas F. Deuel, Arlen Thomason, and Glenn F. Pierce

351 **The Effects of the Bioflavonoid Quercetin on Squamous Cell Carcinoma of Head and Neck Origin**
Manuel H. Castillo, Eddie Perkins, John H. Campbell, Ralph Doerr, James M. Hassett, Chithan Kandaswami, and Elliott Middleton, Jr.

THE GAMMEX SURGICAL GLOVE.
FROM ANSELL MEDICAL.

The Facts
Every glove is electronically tested for greater patient and user safety.

Are others?

Every glove has a reinforced, tapered cuff for firmer anchorage.

Do others?

Every glove is manufactured with a low modulus latex for increased comfort.

Are others?

Every glove has improved sensitivity in palm and fingertip areas.

Do others?

Every glove is micro-textured for better instrument grip.

Are others?

The world's most reliable glove is now available direct from the world's leading glove manufacturer. For more of the facts, contact Ansell Medical.

INJURY

The British Journal of Accident Surgery

Editor: **O N Tubbs** FRCS FICS The General Hospital, Birmingham, UK

If you are responsible for the surgical management of accident cases, you need a journal known to be an authority on accident surgery and trauma, a journal with an international reputation, a journal that will not only help you make the right diagnosis but will also tell you how to deal with it.

Injury, The British Journal of Accident Surgery, is that journal. It will help you to recognise and treat all aspects of trauma, from injuries of the head, chest and abdomen, to fractures and soft tissue injuries.

Regular features include:

- **case reports**
- **abstracts**
- **book reviews**
- **letters**

Injury will keep you up to date with basic research and work on accident prevention as well as common everyday problems from road traffic accidents, gunshot and stab wounds to industrial accidents.

SUBSCRIBE TODAY AND DISCOVER HOW BEST TO MANAGE YOUR TRAUMA CASES!

Injury is published bi-monthly

ISSN 0020-1383

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support, (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be. author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag 1981: 123–63.

Data Sheet

PDS* and PDS II (Polydioxanone) Sterile Monofilament Synthetic Absorbable Suture

Presentation

PDS and PDS II (Polydioxanone) Monofilament Synthetic Absorbable Sutures are prepared from the polyester poly (p-dioxanone). The empirical molecular formula of the polymer is $(C_4H_6O_3)n$. PDS (Polydioxanone) sutures are coloured by adding D & C Blue No. 6 during polymerisation. PDS II (Polydioxanone) sutures are coloured by adding D & C Violet No. 2. PDS II sutures may also be manufactured undyed (clear). PDS and PDS II (Polydioxanone) are available attached to stainless steel needles of various types and sizes, and are sterilised by ethylene oxide gas.

PDS and PDS II (Polydioxanone) sutures are relatively inert, non-antigenic, non-pyrogenic and elicit only a mild tissue reaction during absorption.

Action: Two important characteristics describe the in-vivo behaviour of absorbable sutures. The first of these is tensile strength retention and the second absorption rate or loss of mass. The general mechanism by which in-vivo degradation of polydioxanone occurs is hydrolysis.

Data obtained from implantation studies in rats show the following absorption profile:

14 days post implantation –
    70% strength remaining
28 days post implantation –
    50% strength remaining
56 days post implantation –
    14% strength remaining

This indicates a significantly longer period of wound support than previously available with an absorbable suture.

The absorption or loss of mass is minimal until about the 90th post implantation day and is essentially complete within 180 days.

Uses

PDS and PDS II (Polydioxanone) monofilament sutures are intended for use where an absorbable suture or ligature is indicated. They may have particular application where longer wound support is required. See strength retention data above.

Dosage and Administration

By implantation.

Contra-indications, Warnings, etc.

These sutures, being absorbable, should not be used where extended approximation of tissues under stress is required or in conjunction with prosthetic devices e.g. heart valves or synthetic grafts.

The safety and effectiveness of PDS and PDS II (Polydioxanone) sutures in neural and cardiac tissue have not been established.

As with all monofilament synthetic sutures, care should be taken to ensure proper knot security.

Conjunctival, cuticular and vaginal epithelium sutures could cause localised irritation if left in place for longer than 10 days. Superficial placement of subcuticular sutures may also be associated with erythema and reaction during the course of absorption.

Pharmaceutical Precautions

Recommended storage conditions are below 25°C, away from moisture and direct heat. Shelf life is 5 years, the expiry date is shown on each pack. Do not re-sterilise the contents of the pack. Unused product from opened packs should be discarded.

As with all sutures, care should be taken to avoid damage when handling. Avoid the crushing or crimping application of surgical instruments such as needle holders and forceps to the strand, except when grasping the free end of the suture during an instrument tie.

Legal Category

Not applicable.

Package Quantities

PDS is available in various lengths in gauge sizes Metric 0.2 to 0.4 (10/0 to 8/0). PDS II is available in various lengths in gauges sizes Metric 0.5 to 5.0 (7/0 to 2). The sutures are packaged in sealed aluminium foil packs and peel apart overwrap pouches. The sales unit is a film wrapped box containing 12 or 24 packs.

Further Information

No suture related adverse reactions were reported during clinical trials, although a number of minor reactions were classified as being of unknown cause.

Product Licence Nos.

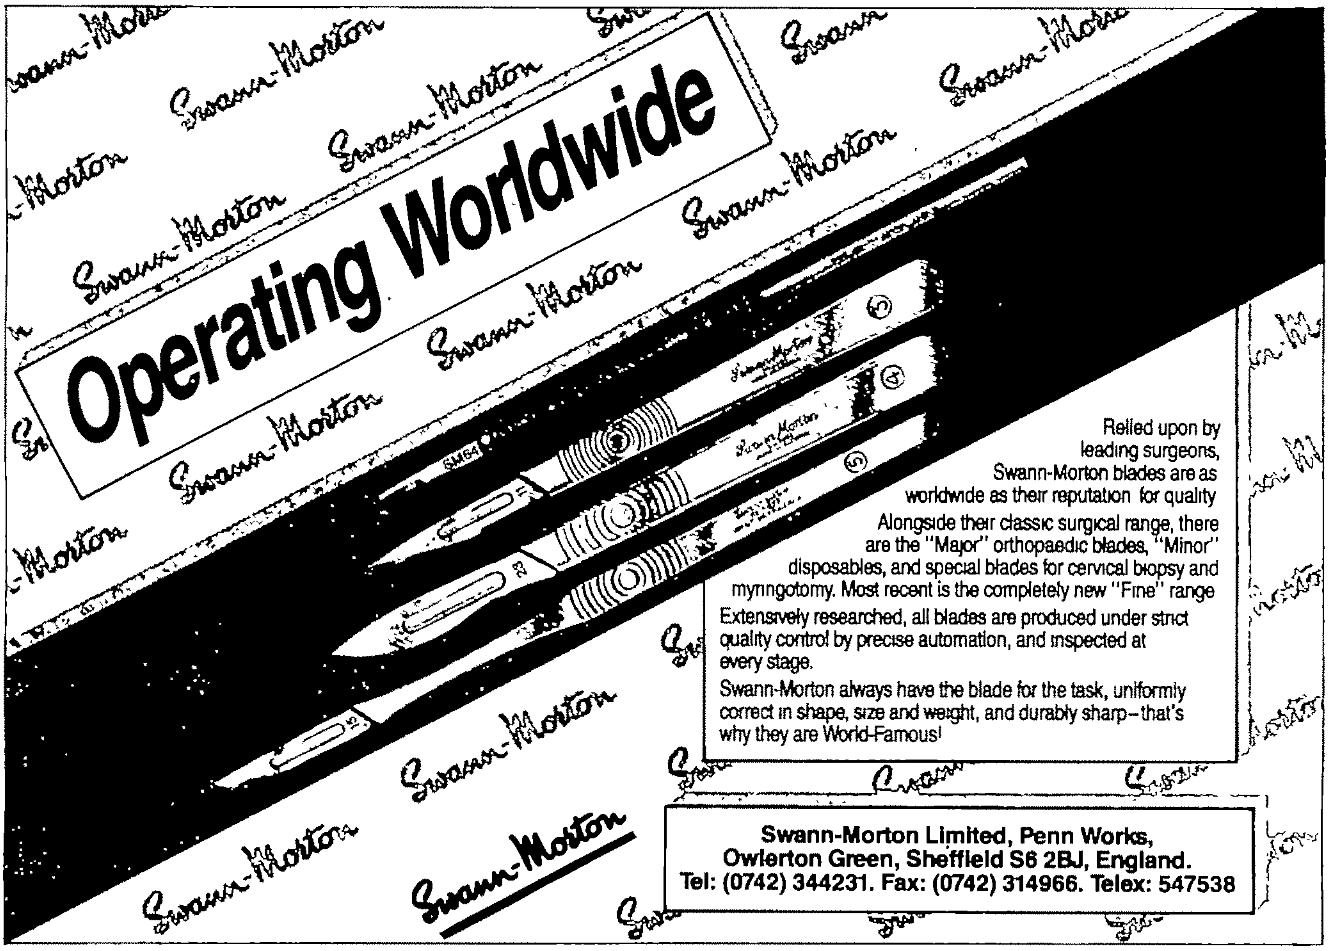
Date of Preparation of Data Sheet – Revised August 1989



Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality. Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp – that's why they are World-Famous!

Swann-Morton Limited, Penn Works,
Owlerton Green, Sheffield S6 2BJ, England.

Royal College of Surgeons of Edinburgh

SECOND SURGICAL MASTERCLASS, AVIEMORE

11–13 March 1990

A residential two-day meeting for consultants and senior registrars in general surgery will be held at the Coylumbridge Hotel, Aviemore, Inverness-shire, from 2.00 pm on Sunday 11 March to 6.00 pm on Tuesday 13 March 1990. Each of the 5 half-day sessions will include lectures, video demonstrations of surgical techniques and the opportunity to practise these on the bench. The meeting will provide an ideal opportunity to improve surgical techniques in the relaxed surroundings of the Scottish Highlands.

PROGRAMME

The surgery of abdominal aortic aneurysms	Miss A O Mansfield, *London*
Gastric cancer – resection and reconstruction	Professor Alfred Cuschieri, *Dundee*
Restorative proctocolectomy – pouch construction	Mr R J Nicholls, *London*
Whipple's Operation	Professor D C Carter, *Edinburgh*
Ivor Lewis Operation for oesophageal cancer	Mr Anthony Watson, *Lancaster*
Simulation in surgical training	Mr Alasdair Munro, *Inverness*

The fee for the Masterclass will be £200 (inclusive of accommodation). Since numbers will be restricted, early application is advisable. Application forms can be obtained from the Clerk to the College, The Royal College of Surgeons of Edinburgh, Nicolson Street, Edinburgh EH8 9DW. Telephone: 031 556 6206 ext. 228.

Your guide for surgical problems in proctology!

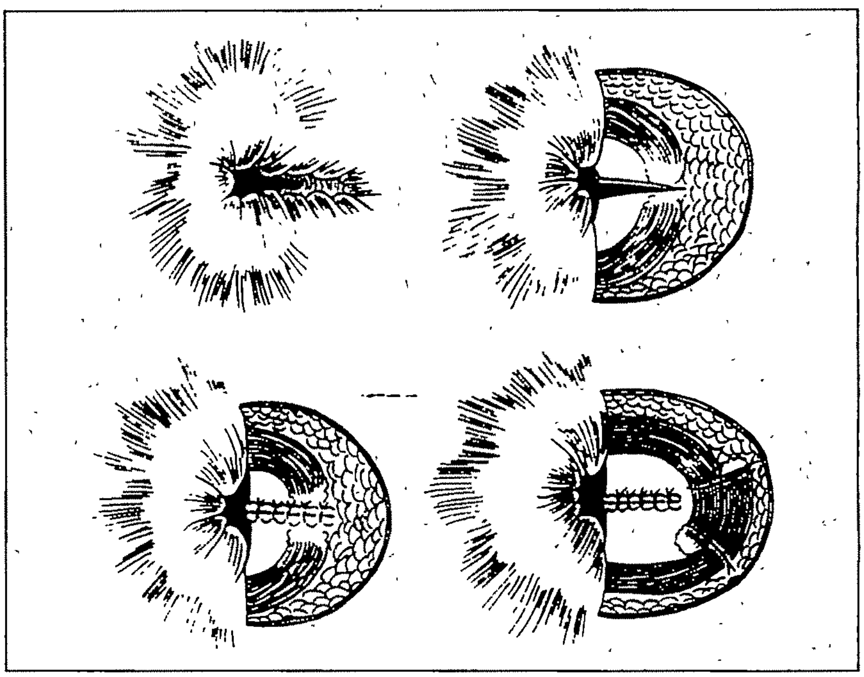
Surgery of Anorectal Diseases

With Pre- and Postoperative Management

With contributions by numerous experts

1990. Approx. 352 pp. 266 figs. 100 tabs. Hardcover DM 248,–
ISBN 3-540-50928-3

Sphinctero-plasty ▶



Here is a practical book dealing with the clinical and therapeutic aspects of anorectal lesions. It is especially written for the colo-proctologist or gastroenterologic surgeon who is faced with an increasing number of precise and specific treatment modalities.
Leading European specialists have contributed to this comprehensive monograph. The beginning chapters cover general aspects such as surgical anatomy, symptomatology, biopsies, and radiological investigations. The following chapters then discuss the various and complex anorectal lesions, from epidemiology and differential diagnosis to surgical treatment and complications. Precise guidelines are given for assessment, and surgical techniques are illustrated in detail. Each chapter is completed with numerous up-to-date references.
The complete information in this book on both common and rare anorectal diseases is particularly important for the practitioner who should know all the possible modalities of conservative and surgical treatment and for the surgeon who should adapt his surgical procedure to the clinical and anatomical findings. This is an excellent addition to every specialist's library.

Gastric cancer: different diseases

Worldwide, gastric cancer remains a leading cause of death from malignant disease. Over the last 50 years, an abundance of literature has accumulated on this disease, highlighting fascinating features concerning the behaviour of a malignancy. Different patterns of disease have evolved to the extent that it has been suggested that the disease in Japan is different from that in the West. More recently, it has become clear that different therapeutic strategies may produce different end results. However it is not clear whether these reflect innate biological differences in tumours or are the result of different treatments.

In the Western world, there has been a significant decline in the incidence of gastric cancer. This is most marked in the United States, but is now being seen in Europe. While still the most common cause of death in Japan, a similar trend has been observed there. Recently, it has been reported that the location of the tumour within the stomach itself is changing. The antrum remains the most common site, but there has been a significant increase in the proportion of lesions at the cardia[1].

Certain clinico-pathological features of the disease have been established that facilitate international comparisons. In all countries, stage I disease is associated with a good prognosis. It is of interest that the Japanese report a survival rate of 98 per cent at five years for patients with tumours of this stage, but most studies from Europe report a five-year survival rate of 70 per cent. This suggests a difference in biological behaviour of these types of tumours in the East and West. However, a paper[2] from the British Society of Gastroenterology indicates that the differences may be in classification rather than behaviour. In a review of 132 early gastric cancers the survival at five years of true early cancers was 95 per cent, but in those which have been reclassified the survival rate is similar to that reported in other studies[3], many of which were retrospective and not subject to pathological review. The Lauren pathological classification[4] has identified two tumour types of different biology, namely intestinal and diffuse. The former is associated with a better prognosis and is more common in areas with a high incidence of the disease. It is also the type of tumour that decreases in frequency with a fall in gastric cancer incidence. Thus, on currently available evidence, tumours do appear to behave differently in the East and West but when comparisons are made between like tumours the results are similar.

A further explanation for different results may lie in management. The Japanese have an aggressive diagnostic policy which has resulted in an increase in the detection of 'early' disease, curable by surgery. Although screening programmes are unlikely to be cost-effective in the West, early diagnosis in high-risk groups has been shown to increase the proportion of early lesions to 20 per cent. Mucosal gastric cancers are symptomatic in 50 per cent of cases and thus, endoscopic diagnosis of dyspeptic patients over the age of 40 is recommended. From this group, patients with mucosal changes such as dysplasia (and possibly atrophic gastritis and metaplasia) are selected for regular follow-up.

Surgery is the treatment for early stage disease and once again the major advances have come from Japan. Two features are of particular note. Firstly, the operative mortality rate in the United Kingdom for total gastrectomy is often in excess of 20 per cent[3]. Specialist centres report figures in the range 1–5 per cent[5]. Results of this kind can only be achieved by the acceptance and development of specialist groups. Secondly, the extent of the surgery is variable and its benefits debatable. The Japanese approach has been to perform extended radical gastrectomy (R2). However, the literature from the West does not support the case that this type of surgery is of benefit and the issue is currently the subject of a Medical Research Council trial.

Consideration must be given to the role of other methods of treatment for gastric adenocarcinoma. Recognition of the importance of early diagnosis and surgery as the prime areas for advance has resulted from the failure of other potential methods of treatment. Disappointingly, cytotoxic chemotherapy has been of no therapeutic benefit and there is no place for its use outside clinical trials[6]. However, the stomach is an endocrine end organ and stomach cancer may yet prove to be a hormone responsive tumour; an exciting development has been the reported[7] benefit of treatment with the H_2-receptor antagonist cimetidine.

In conclusion, there is now strong evidence that gastric cancer may occur in different biological forms, that there are changing patterns of disease, and that diagnostic and therapeutic strategies may influence the long-term results. It is these features which produce the apparent differences between East and West and which hold the key to future advances in management.

Ambulatory hernia surgery

In the United States ambulatory hernia surgery became a fact of life when Medicare, the federal programme that reimburses hospitals and physicians for medical care of the elderly, finally followed the lead of other third party payers and disallowed reimbursement for hospitalization of those over 65 years old undergoing elective inguinal hernioplasty. This dictate was less Draconian than it first appeared because nearly all groin hernioplasties were already being performed preferentially on a day-patient basis. This timely method of performing inguinal hernioplasty benefits everyone. It is safe, convenient, efficient, economical and very popular. Furthermore, the mere idea of ambulatory hernia surgery softens the emotional impact of the operation and thereby reduces disability by encouraging the patient to get on with his life. In the beginning, financial incentives were necessary to promote acceptance. However, it soon became obvious that the majority of the patients preferred not to be admitted as in-patients.

Making ambulatory hernia surgery easy and unintrusive for the patient is primarily the responsibility of the surgeon. Of course, ambulatory units must be user-friendly, but in the end how the patient 'does', as measured by disability, morbidity, and chance of recurrence depends almost solely on the technical skills of the surgeon, the hernioplasty employed, the mode of anaesthesia and attention to minute details. These important matters for concern have been largely overlooked. They need addressing for they define good surgery.

Ambulatory hernia surgery does not preclude general, spinal or epidural anaesthesia. However, the perfect anaesthesia for a primary, reducible inguinal hernia in the non-obese is local anaesthesia. In routine cases, the assistance of an anaesthetist is usually not necessary and only adds to the cost. Furthermore, local anaesthesia eliminates the need for costly preoperative testing. Informed patients actually prefer local to general anaesthesia and like to have the operation without missing their morning cup of coffee. Surgeons ought to like local anaesthesia because it shortens the time between cases and challenges their technical ability. Local anaesthesia is safe, and furthermore it allows immediate ambulation and early discharge from the ambulatory unit. Much has been written about the technique of administering the anaesthetic. However, the comfort of the patient has more to do with the surgeon's ability to operate gently and to dissect sharply than it has to do with his technical skills with a syringe and needle filled with local anaesthetic.

The burning pain caused by the administration of the local anaesthetic can be eliminated by neutralizing the agent. This also greatly enhances the anaesthesia and reduces the quantity of anaesthetic required. The 8·4 per cent sodium bicarbonate solution from the operating room emergency tray may be used if vials of small quantity are not available. The pH of plain local anaesthetic is about 6.0, and simply drawing 1 ml of the sodium bicarbonate solution into a 10 ml syringe filled with 9 ml of plain local anaesthetic brings the pH to a comfortable value of about 7.5. The pH of local anaesthetic with adrenaline is about 4.0 and therefore 2.5 ml of the sodium bicarbonate solution are required.

The selection of the hernioplasty is important. If other things are equal, the hernioplasty producing the least disability ought to be the procedure of choice. The hernioplasty with the reputation for the shortest convalescence is the Shouldice hernioplasty. In fact, it was E. E. Shouldice who, more than 45 years ago, pioneered short stay hernioplasty and thus paved the way for day hernia surgery. He held the view, long before other surgeons concurred, that patients could not wilfully hurt themselves. Acting accordingly, he discharged his patients after a couple of days and encouraged them to resume all physical activities as soon as their discomfort permitted. This attitude, coupled with a low chance of recurrence, brought many thousands of patients to his Toronto clinic. The hernioplasty developed at his hospital by co-workers Obney and Ryan actually complements this attitude. The Shouldice hernioplasty's good results have been confirmed by many and are attributable to the use of continuous sutures which distribute tension evenly, to the imbrication of the structurally important innermost aponeurotic–fascial layer resulting in a strong seam, and to a repair which is essentially tension free[1–3]. The operation is easy and is a joy to perform. What remains astounding is how many surgeons still disbelieve the good results and stubbornly adhere to techniques which do not match the Shouldice hernioplasty and are less well suited for day surgery.

Most patients with bilateral hernias can have them repaired at the same time provided that the hernias are not too large and that the time for the awake patient on the uncomfortable operating room table is not too long. There is no advantage in separating the procedures and patients are disappointed at the thought of two separate periods of disability. Surprisingly, the disability from bilateral hernioplasties is not essentially different from that of unilateral hernioplasty. However, a prudent surgeon would delay repair of a second indirect hernia if for any reason the indirect sac of the first side had to be completely dissected from the cord. This occurs with sliding indirect inguinal hernia sacs.

Morbidity prolongs convalescence and disappoints patients. However, the belief that

0007-1323/89/121228–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

hospitalization will protect the patient from complications, promote sound wound healing, and reduce the chance for recurrence has no basis in fact for primary inguinal hernia surgery. Morbidity begins in the operating room. It cannot be overemphasized that expeditious, meticulous, precise dissection reduces discomfort, minimizes complications and promotes primary healing. In general drains should be avoided and dead space eliminated. Haemostasis must be complete and achieved without necrosing the tissues excessively with the electrosurgical unit or by mass ligation. The overwhelming desire of assistants to draw up tightly sutures which approximate tissue must be assiduously avoided. Even the skin closure is important. Steri-Strips (3M, St. Paul, Minnesota, USA) are ideal. They are quick to apply, painless, removable by the patient, promote healing, and reduce the chance of infection. Steri-Strips do not pinch the skin closure and are therefore not haemostatic. Patients may be alarmed by skin bleeding which saturates the wound dressing. This drawback can be prevented by supplementing the Steri-Strips with a subdermal monofilament suture of very fine absorbable synthetic material.

Ischaemic orchitis and its sequel, testicular atrophy, angers men of all ages and invariably produces litigation. It is caused by thrombosis of the spermatic cord induced by dissection trauma to the pampiniform plexus and is not owing to the tightness of the deep ring reconstruction or some occult genital infection as some surgeons have speculated[4]. The complication can be minimized by careful sharp dissection of the cord (never blunt), limiting dissection of the spermatic cord to the inguinal canal only, and avoidance of dissection in the distal portion of indirect inguinal hernia sacs whenever possible.

Recurrent hernias and hernias associated with connective tissue disorders are at high risk of recurrence following repair. Most of them are manageable in ambulatory hernia centres, and for success a prosthesis is advisable. Approaching these difficult hernias by the preperitoneal route has several important advantages. One advantage is the obvious fact that the preperitoneal space is the ideal site in which to implant the prosthesis. The preperitoneal approach also eliminates dissection of the previously mobilized, scarred and splayed spermatic cord and, for all practical purposes, avoids the complication of testicular atrophy. Finally the preperitoneal approach exposes all of the anatomy of the posterior wall of the groin and allows the surgeon to implant a large prosthesis which can extend far beyond the sutured, or sometimes even unsutured, myo-aponeurotic defect in the abdominal wall.

A useful technique which facilitates implantation of a prosthesis in the preperitoneal space is parietalization of the spermatic cord[5]. The technique consists of dissecting the peritoneum away from the elements of the spermatic cord. The vas deferens and testicular vessels will then lie against the wall of the pelvis and the prosthesis can cover them and the deep ring completely. This makes a slit in the mesh to accommodate the cord unnecessary. The secret of successful prosthetic hernioplasty is to make the mesh sufficiently large. The currently popular repairs using patches and plugs of mesh are often inadequate because the prostheses are too small and hernias return through adjacent areas of weak tissue. Recently, promising techniques have been described[6,7]. For ambulatory repair the best access to the preperitoneal space is through a unilateral transverse incision centred over the rectus muscle 2–3 cm below the bispinous line but well above the deep ring. General anaesthesia is usually necessary because of the extensive dissection. Despite the dissection, patients experience very little postoperative discomfort, perhaps because the large prosthesis provides support.

The development of ambulatory hernia surgery is a great step forward. The results, however measured, are very surgeon dependent. If done correctly and carefully, patients will be grateful and appreciative and society will benefit by freeing up limited hospital resources for the critically ill.

Local low dose intra-arterial thrombolytic therapy: the risk of stroke or major haemorrhage

**D. C. Berridge,
G. S. Makin and
B. R. Hopkinson**

Department of Vascular Surgery, University Hospital, Nottingham, UK

Correspondence to:
Mr D. C Berridge, E Floor, West Block, University Hospital, Nottingham NG7 2UH, UK

The use of local low dose thrombolysis is gradually increasing. Most experience is with streptokinase, although newer agents such as recombinant tissue plasminogen activator (rTPA) may offer more effective lysis with reduced complications. We have reviewed the experience documented in 19 prospective series published between 1974 and 1988 in an attempt to define the incidence of stroke, major haemorrhage and minor haemorrhage. The overall risk of stroke was 1·0 per cent of patients (14 cases). Major haemorrhage occurred in 5·1 per cent of patients (71 cases) and minor haemorrhage occurred in 14.8 per cent (92 out of 620 cases). There was little difference between the two thrombolytic agents, although the experience with lower doses of rTPA suggests it may offer a reduced risk of haemorrhagic complications. It is essential that all studies concerning thrombolysis should give their exclusion and inclusion criteria in full to allow an accurate appraisal of haemorrhagic complications, with the hope of improved patient selection and reduced morbidity in the future.

Keywords: Thrombolytic therapy, peripheral vascular disease

Interest in peripheral arterial thrombolysis is increasing. The great advance was the realization that comparatively low doses (5000 units h^{-1}) of streptokinase[1] could achieve an increased success of thrombolysis when administerd via an indwelling intra-arterial catheter, compared with conventional systemic thrombolytic therapy (100 000 units h^{-1})[2]. Since this report, a variety of agents and doses have been used in attempts to improve thrombolytic success further, and to achieve a reduction in the incidence of haemorrhagic complications.

In published series exclusion and inclusion criteria for thrombolytic therapy are difficult to evaluate as they are often not given[1,3,4–8], or are inexact, such as 'recent CVA' (cerebrovascular accident)[3,9]. Some use a limit of 'less than 2 months history of CVA'[10–12] or 'less than 12 months history of CVA'[13–15]. The National Institutes of Health Conference[12] suggested that a history of a stroke within the preceding 2 months is an absolute contraindication but made no further recommendation. A history of a previous embolic stroke is no absolute safeguard in thrombolytic therapy. In a prospective series of patients with acute stroke in whom embolus accounted for 31 per cent of presentations[16], 5 per cent of the total developed intracranial haematoma, confirmed by computed axial tomography and/or angiography. In addition, differing post-thrombolysis drug therapies (aspirin, dipyridamole, heparin, warfarin) make an accurate determination of haemorrhagic risk difficult to assess. Monitoring of fibrinolytic parameters, in particular plasma fibrinogen levels <100 mg ml^{-1}, may help to predict incipient haemorrhage. In this way Totty[17] may have avoided significant haemorrhage in three patients, whose fibrinogen levels fell to <100 mg ml^{-1}, by treating them with cryoprecipitate.

We have reviewed the experience with peripheral arterial thrombolysis in 19 prospective series published between 1974 and 1988. Early papers have been omitted from the analysis where a later report exists, to avoid overlap of clinical material.

Clinical experience

Nineteen series dealing with local low dose intra-arterial thrombolytic therapy, published between 1974 and 1988, and involving 1401 patients have been reviewed[1,3–21]. The majority of series describe experience with the use of streptokinase (1224 patients) with only 177 patients receiving intra-arterial recombinant tissue plasminogen activator (rTPA). The usual dose of streptokinase was 5000 units h^{-1}, although some centres used up to 10 000 units h^{-1}, as a continuous low dose intra-arterial infusion. The dose of rTPA, however, was rather more variable as is to be expected in initial trials with this drug. Doses used varied from 0·25 mg h^{-1} (Reference 10) to as high as 10 mg h^{-1} (Reference 15). The later reports confirm that the lower doses appear as efficacious as the higher doses[12,14,15]. Care should be taken in comparing the relative risks of the two agents as none of these reports is a randomized comparison of these agents and experience with rTPA is still limited and its dose regimens are still being evaluated.

For the purposes of this review, major haemorrhage has been defined as haemorrhage requiring transfusion, or causing hypotension, or requiring specific treatment in the form of fresh frozen plasma, cryoprecipitate or antifibrinolytic drugs. Minor haemorrhage has been defined as any other haemorrhage not requiring specific replacement therapy or transfusion and not causing hypotension. Such haemorrhage was usually in the form of a small or moderate sized haematoma around the point of entry of the catheter.

Stroke

There was a total of 1401 patients in the collected series, 14 (1·0 per cent) of whom suffered a haemorrhagic stroke. Of these, 11 occurred after streptokinase therapy (*Table 1*) and three after rTPA (*Table 2*). There was no statistically significant difference between the drugs in this report. It is impossible to estimate

Values in parentheses are percentages. * Four series[3,7,19,21] do not report incidence of minor haemorrhage and have been excluded

how many haemorrhagic strokes would have occurred naturally as there are no placebo groups available.

Major haemorrhage

Major haemorrhage occurred in 71 (5·1 per cent) patients overall: in 62 following streptokinase therapy and in 9 following rTPA. Again, there is no statistically significant difference between the drugs.

Minor haemorrhage

Minor haemorrhage usually occurred as a haematoma around the catheter entry site. This affected 92 patients overall (*Table 3*). Streptokinase therapy resulted in 64 patients with minor haemorrhage. Four series[3,7,19,21] were not included in these figures as they did not report the incidence of minor haemorrhage. Minor haemorrhage following rTPA affected 28 patients.

There is no obvious advantage in terms of reduction of haemorrhagic complications from the use of the relatively fibrin specific rTPA and, indeed, there is no statistically significant difference between the two agents with respect to any of the complications studied. However, it would be wrong to draw too many conclusions on the comparative safety of rTPA compared with streptokinase on the basis of this review, as the results for rTPA include all the early work when doses were still comparatively high. Recent experience with lower doses is considerably more favourable. Of the 177 patients (*Table 3*) who received rTPA, the last 61 received much lower doses without any stroke occurring and with only one patient experiencing major haemorrhage.

Discussion

The risks following peripheral local low dose arterial thrombolytic therapy are difficult to assess owing to the plethora of differences in methodology between different centres. Nevertheless, we do need to have some perspective on the risks of haemorrhage and, in particular, stroke, not only to allow adequate informed consent, but also to compare these risks with those following either the systemic use of thrombolytic agents or surgery. Analysis of published data in terms of total dose of lytic agent used is meaningless owing to the relatively short half-lives of these agents and the variation in duration and route of administration.

Previous use of intravenous streptokinase in high doses (100 000 units h^{-1}), following a loading dose of 1 250 000 units, produced lysis in only one-quarter of patients[2]. In the same study major haemorrhage occurred in 18·8 per cent of patients and was 'probably the cause of death' in 7 per cent. Strokes occurred in 5·9 per cent of patients. This report has been referred to by Aldrich *et al.* who inexplicably only mention three haemorrhages and two strokes[22].

In an attempt to reduce the frequency of haemorrhagic complications and stroke, while achieving a high thrombolytic success rate, the search continued for more fibrin specific agents. Acetylated streptokinase complex was developed. Initial animal studies appeared promising but when it was used as an intravenous thrombolytic agent, the incidence of haemorrhagic complications was unacceptably high and the success rate of lysis was poor[23]. Tissue plasminogen activator showed considerable fibrin specificity, however it was initially available only in small impure quantities from human uterine[24] or Bowes melanoma cell lines. Highly purified TPA was subsequently produced from this cell line allowing the gene of TPA to be cloned[25]. This led to the development, using genetic engineering, of recombinant tissue plasminogen activator (rTPA) which was soon found to have the same fibrin specificity and thrombolytic properties as the natural substance[26]. Fibrin bound plasminogen activates rTPA and circulating inhibitors such as α-2-antiplasmin prevent or at least reduce its systemic activation. Despite comparatively low local doses, a progressive systemic response is still seen with streptokinase (at a dose of 5000 units h^{-1} after 4 h) and with rTPA. However, with the latter it is both delayed and significantly reduced[27].

Clinical experience with rTPA in peripheral arterial thrombolysis is still limited. The published reports so far highlight the disparity in techniques, doses, exclusions and indications between different centres. However, in all centres using rTPA the recommended doses are becoming lower. Graor *et al.*[13] initially used 0·1 $mg\,kg^{-1}\,h^{-1}$, and have subsequently shown that 0·05 $mg\,kg^{-1}\,h^{-1}$ is equally effective[14]. Similarly, Verstraete *et al.*[15] reported a multicentre series, initially using 10 $mg\,h^{-1}$. Reduction of this dose to 5 $mg^{-1}\,h^{-1}$ and then 3 $mg\,h^{-1}$ in their own centre does not appear to have reduced the success of the procedure. In Nottingham[11], a small study with doses between 0·25 and 2·5 $mg\,h^{-1}$, showed that effective lysis could be achieved with even lower doses. We have followed up this with a further series using 0·5 $mg\,h^{-1}$ and have achieved a success rate of 74 per cent for thrombolysis, without major haemorrhagic complications or stroke[12].

It is illogical to assume that the most fibrin specific 'ideal' agent will be free from all risk of stroke and haemorrhage. Patients will continue to have silent strokes and asymptomatic or unrecognized peptic ulceration in association with a haemostatic platelet/thrombus plug. The 'ideal' agent must recognize this as a legitimate target and will lyse this plug as readily as it will the peripheral arterial thrombus it was intended to treat. The relative maturity of the two different sites will determine if and when the complication will occur. For example, when thrombolytic agents are used in the presence of Dacron® (Du Pont) grafts, massive haemorrhage occasionally ensues. These grafts may take many years to become completely sealed with a neointima and, in the meantime, part of their integrity relies on thrombus incorporated in the interstices of the graft material. If the dose of lytic agent is either high enough, or is administered for long enough, lysis of the lining thrombus occurs with the formation of a permeable graft[28,29]. Whether the 'ideal' agent is administered systemically or locally via an indwelling intra-arterial catheter will have some bearing, as in the latter case thrombus prevents the flow of blood distally into the run-off or collateral vessels, such that only small amounts of the lytic agent will escape into the main circulation and cause lysis of distant thrombus.

Patient selection has a major role to play in reducing the complication rate associated with this technique, but exclusion criteria must not be so strict that patients who may benefit from this form of therapy are denied it. Those who are at greatest risk from conventional treatment (previous strokes, ischaemic heart disease, chronic obstructive airways disease, acute peripheral arterial thromboses), are the ones who should be considered for peripheral arterial thrombolysis as an alternative therapy.

The wisdom of the concurrent use of heparin remains uncertain. Some investigators use a low dose infusion to attempt to reduce the incidence of pericatheter thrombosis. Others use higher doses to achieve an activated partial thromboplastin time approximately double that of the control. Some do not use it at all. The augmentation of lytic effect, associated with higher doses of heparin[30], does not occur with lower dose schedules, but the newer low molecular weight heparin fragments may offer enhancement at much lower doses[31]. It has been shown that a systemic effect is produced using low dose streptokinase after as little as 4 h[26] and it might seem that heparin would only add risk without any advantage. The question should be answered by current trials.

In conclusion, the overall stroke rate following low dose peripheral arterial thrombolysis is 1·0 per cent, with a 5·1 per cent risk of haemorrhage requiring transfusion and/or correction with coagulation factors. We must await the completion of further trials using the newer agents such as rTPA to determine if they offer a lower incidence of complications when used at lower doses. All reports concerning the use of thrombolytic agents in peripheral arterial thrombolysis should clearly state the exclusion criteria used and should discuss the complications found in relation to the risk factors, as suggested at the National Institutes of Health conference[32]. Only then will we be able accurately to assess the risk posed by peripheral arterial thrombolysis with different agents. There is insufficient information given in the published studies to determine whether any previous history of stroke should be regarded as an absolute contraindication for this form of therapy.

This review evaluates selective enzymes and blood tests available for the diagnosis and prognosis of acute pancreatitis. It is concluded that serum amylase and lipase measurements represent the best available diagnostic methods. Newer alternative assays still require careful evaluation

Keywords: Acute pancreatitis, diagnosis, prognosis, amylase, lipase, enzymes, plasma markers

Acute pancreatitis still represents a major diagnostic and therapeutic challenge. Not only is the diagnosis controversial and often unsatisfactory in the emergency setting, but also the severity of the disease is often underestimated as suggested by McMahon *et al.*[1], who pointed out that only one out of three severe cases of acute pancreatitis is recognized to be severe at an early stage of the disease. Wilson *et al.*[2] recently reported that 42 per cent of their fatal cases of acute pancreatitis did not have a correct diagnosis prior to necropsy.

The determination of serum amylase is the basis for definition of acute pancreatitis in practically all studies[3]. Most cases lack surgical or post-mortem confirmation, thus it is possible that the frequency of the diagnosis is overestimated or underestimated in many series. Only recently have non-invasive techniques, such as contrast-enhanced computed tomography (CT) scanning using high resolution, fast, third or fourth generation scanners enabled direct visualization of the pancreas and its surroundings; such CT scans represent to date the most accurate method of diagnosing acute pancreatitis[3–5]. During the acute phase of the disease CT scanning is far superior to ultrasonography[5] and even perhaps to laparotomy[6]. CT scanning, however, is not always available and cannot be performed in all instances where acute pancreatitis is suspected clinically because of its high cost[4]. The purpose of the present paper is to review the value of enzymatic markers and some other selective tests and to propose guidelines with which to establish the diagnosis and severity of acute pancreatitis.

Amylase

Total serum or plasma amylase

Determination of total serum amylase remains, for most investigators, the cornerstone of the diagnosis of acute pancreatitis since this enzyme is universally regarded as the most practical and sensitive single screening test[3,7]. Amylase is an enzyme with a molecular weight of about 50 000 Da[7,8] found in the blood for the first time in 1846 by Magendie[7] and first measured quantitatively in animals by Foster in 1867[9]. Its importance in pancreatic disease was suggested in 1909[10] and its role in acute pancreatitis definitively demonstrated by Elman *et al.* in 1929[11]. More than 200 methods of determination of serum amylase have been described[7,8]. The most common of these are the amyloclastic (e.g. Wohlgemuth, Nephelometry) and the saccharogenic methods (e.g. Somogyi) and, more recently, methods using dye substrates (e.g. Russel, Phadebas) and chromogenic substrates[7,8]. However, no international reference method has yet been adopted and since various substrates are used, comparison of amylase determinations between different centres is often hazardous.

Plasma amylase is believed to rise within 24 h of the onset of acute pancreatitis[7,12,13], initially as a result of direct venous drainage of the pancreas and its peripancreatic tissue and later by lymphatic drainage through the thoracic duct[14]. The role of the transperitoneal absorption of the enzyme in increasing the plasma level is probably less important than previously reported[15,16]. Return to normal values is generally noted within 5 days[7,8,12,13]. Normalization can sometimes occur very rapidly, indicating early resolution of the disease or, less frequently, extensive destruction of the pancreas with cessation of pancreatic amylase production[17,18]. The 'threshold' diagnostic level of serum amylase is often arbitrarily chosen and varies considerably from one study to the next, ranging from one to nine times the upper reference value[17]. Higher levels tend to enhance diagnostic specificity by eliminating false positive results; this, of course, is to the detriment of the diagnostic sensitivity of the enzyme. To evaluate the specificity of total serum amylase, Weaver *et al.*[19], through the use of isoamylase determinations, have shown that 18 out of 57 cases of hyperamylasaemia associated with abdominal pain were, in fact, not due to acute pancreatitis. Koehler *et al.*[20] reported similarly that ten of 37 patients with a clinical diagnosis of acute pancreatitis and hyperamylasaemia had incorrect diagnoses in that the elevated serum amylase originated from extrapancreatic tissue. Indeed, about one-third of the cases of hyperamylasaemia and abdominal pain are in fact not due to acute pancreatitis, giving a diagnostic specificity for serum amylase approaching 70 per cent[3]. Abnormal levels of serum amylase are secondary to increased production or decreased catabolism, as can occur in renal failure[21] and in liver dysfunction[22]. However, renal impairment alone has little effect on serum amylase concentrations since in such situations 75 per cent of amylase is metabolized via an extrarenal mechanism, possibly involving the reticuloendothelial system[8,13,23]. The list of non-pancreatic conditions accompanied by hyperproduction of amylase is constantly increasing (*Table 1*).

The sensitivity of serum amylase in acute pancreatitis is extremely difficult to evaluate since most authors have based the definition of the disease on the hyperamylasaemia itself, resulting in a very low incidence of normoamylasaemic acute pancreatitis. Only some cases found incidentally during surgery or autopsy are occasionally mentioned in the literature and represent commonly less than 5 per cent of all acute pancreatitis cases[17]. In rare studies and small series, the incidence of normoamylasaemic acute pancreatitis can exceed 10 per cent[48]. Spechler *et al.*[49] noted a normal amylase level on admission in 32 per cent of 68 cases of acute alcoholic pancreatitis. This exceptionally high rate of normoamylasaemic acute pancreatitis was further questioned since in only two-thirds of these cases was the diagnosis supported by ultrasonography or CT scan findings[50]. Recently, using systematic early CT scanning to ascertain the clinical diagnosis of acute pancreatitis, irrespective

of level of serum amylase, one of the present authors found an incidence of 19 per cent of normoamylasaemic acute pancreatitis[17].

Isoamylase

Measurement of amylase isoenzymes has been attempted to improve the clinical specificity of the total amylase[21,51–53]. α-Amylase is an enzyme that acts on starch to split α-1–4 glucosidic bonds randomly. It is found in humans and in animals, while β-amylase is specific to plants[7,54]. In humans, electrophoretic techniques enable the distinction between the two main types of isoamylases: pancreatic type (p-type, AMY 2) and salivary type (s-type or AMY 1). Their respective fractions in the blood vary among individuals[53–55]. However, normally, pancreatic amylase represents about 40 per cent of total amylase and is quite specific to the pancreas[51,54]. Recently, three different kinds of p-isoamylases have been differentiated by electrophoresis, of which the p-3 fraction has been noted to be the most specific for AP[55,56]. Conversely, salivary amylase is totally non-specific and is found in all tissues that contain amylase[7,27,37,51]. Finally, an electrophoretically atypical amylase termed 'Y-type' has been isolated and found to be associated with some carcinomas[54].

Isoamylase determination has little if any value in enhancing the diagnostic sensitivity (i.e. when amylase level is normal the preponderance of p-type isoamylase rarely unmasks acute pancreatitis), although some authors have found it to be of use in cases of slight hyperamylasaemia[51,53]. Its major advantage resides in the important boost in specificity allowing differentiation between pancreatic and extrapancreatic isoamylase[51,53,55,56]. As mentioned above, recent clinical studies have shown that isoamylase profiles can change the diagnosis of acute pancreatitis in up to one-third of hyperamylasaemic patients[19,20]. However, conditions other than acute pancreatitis, especially abdominal emergencies (such as mesenteric infarction, intestinal obstruction and perforated peptic ulcer) and some cancers (e.g. ovarian neoplasm) are occasionally associated with p-type hyperamylasaemia[27,35]; in such circumstances isoamylase profiles will not distinguish acute pancreatitis from these conditions.

The method used for isoenzyme determinations is of critical importance: whereas a number of accurate electrophoretic and chromatographic techniques have been validated, the currently popular rough approximation based on differential inhibition of s-type isoamylases by a wheat protein inhibitor is probably less reliable[53,57–59]. In the emergency setting isoamylase determination is rarely used since efficient measurements are often time-consuming[3,17,60], however new rapid tests should still be evaluated for their ability to enhance the diagnostic accuracy of total amylase.

Macroamylase

Amylase bound to an abnormal protein to form a high-molecular complex was first described by Wilding *et al.* in 1964[61]. The analysis of isoenzymes has revealed that both p-type and s-type isoamylase could be incriminated. The binding protein can be an IgG as well as an IgA[62,63], and the molecular weight of this complex ranges from 150 000 Da to more than one million Da; a molecule too large to be excreted by the kidney[61–63]. Thus, the characteristic of macroamylasaemia is an elevated plasma amylase in the absence of elevated amylasuria. A similar presentation could theoretically be encountered in conditions other than macroamylasaemia such as renal dysfunction[63]. An amylase:creatinine clearance ratio (Cam:Ccr) of less than 1 per cent has been proposed as pathognomonic of macroamylasaemia[64]. However, a normal Cam:Ccr does not exclude macroamylasaemia – as is the case when the ratio for serum activities of macroamylase to normal amylase is low[63]. Isolated hyperamylasaemia accompanied by normal values of other pancreatic enzymes (e.g. lipase) should alert the clinician to the possibility of macroamylasaemia. However only appropriate and specific laboratory measurements can ascertain the presence of macroamylase[65].

The prevalence of macroamylasaemia in the normal population occurring as a persistent or transient event ranges between 1 and 2 per cent[63,66], representing a benign chemical derangement that has not yet been consistently correlated with any particular disease[7,63,66]. Macroamylasaemia has been incriminated in 6–28 per cent of patients with chronic hyperamylasaemia of unknown origin[57,67]. In acute pancreatitis, macroamylasaemia has been found in no more than 3 per cent of the cases[63,66].

Serum amylase and hyperlipidaemia

Lipaemic serum has been reported in up to 20 per cent of cases of acute pancreatitis associated with alcohol abuse[68,69]. In such situations, hyperamylasaemia is often difficult to evaluate. The hyperlipidaemia interferes with the amylase assay leading to a spuriously normal result; plasma triglycerides either suppress or inhibit serum amylase activity[51]. The spuriously normal amylasaemia usually can be unmasked by serial dilutions of the plasma[51,68,69], although this simple method is not universally accepted[70]. Cam:Ccr ratio has been found to be less influenced by hyperlipidaemic serum and an elevation of the ratio was considered useful in making the correct diagnosis[51]. On the other hand, lipaemic serum represents a difficult diagnostic problem in acute pancreatitis regardless of whether hyperlipidaemia is secondary to pancreatitis or the cause of it, since the presence of hyperlipidaemia is often undetected before the pancreatitis episode[68–70].

Urinary amylase

Determination of amylase in urine has sometimes been considered to be more accurate than serum amylase estimation, and was selected by some authors to support their diagnosis of acute pancreatitis[71,72]. Although rising slightly later, hyperamylasuria commonly parallels hyperamylasaemia, and the same limitations of specificity and sensitivity therefore apply[3,7]. The clearance of amylase or the estimation of the rate of urinary amylase output is subject to errors inherent in difficulties of collection[71]. Furthermore, amylase is unstable in urine and unpredictably variable results are obtained from stored samples[73]. A recent rapid colorimetric test for urinary amylase (Rapignost®, Behring Werke, Marburg, FRG) has been found to be as accurate as any other enzyme determination in the diagnosis of acute pancreatitis in the emergency setting[74,75]. The test can be readily performed by medical or nursing staff over a 3-min period and is extremely easy to interpret and could represent the method of choice for the screening of the disease. However, other studies comparing the results obtained by the Rapignost amylase test with the measured serum amylase level were less encouraging with some false positive results and a sensitivity which was estimated to be less than 70 per cent[76,77].

Amylase/creatinine clearance ratio

The Cam:Ccr ratio was first proposed by Levitt *et al.* in 1969 as a means of detecting the increase of amylase clearance rate during acute pancreatitis[78]. Amylase passes through the glomerular membrane and, under normal conditions, approximately 75 per cent of the filtrate is reabsorbed in the proximal tubule. The clearance of p-type isoamylase is higher than that of s-type, but the magnitude of the difference remains controversial[23,79]. The immediate advantage of the Cam:Ccr ratio determination over the direct clearance measurement is the absence of the need for accurate urine volume collection, and short collection time, thus permitting a 'spot or catch' urine sample to be of value[7]. However, it is difficult to achieve true simultaneity between blood and urine sampling in common nursing practice.

The normal ratio is approximately 2 per cent and an increase above 6 per cent has been proposed as diagnostic of acute pancreatitis[79,80]. The sensitivity of this ratio was first considered as excellent since it was thought that in the presence of normal amylasaemia a normal ratio excluded the diagnosis of acute pancreatitis[79]. Subsequently, Warshaw *et al.*[80] emphasized that the increase of the ratio was specific for acute pancreatitis; no false positive values were recorded in 44 cases of hyperamylasaemia not related to pancreatic disease. Later on, the usefulness of Cam:Ccr ratio in acute pancreatitis diagnosis was questioned by several investigators and its value is now generally considered to have been overestimated[3,42,71,81,82]. Cases of acute pancreatitis with a normal ratio were reported[64,81] and a number of causes other than acute pancreatitis were associated with a high ratio, namely the postoperative period[42,82], diabetic ketoacidosis[83], burns[83,84], cancer of the pancreas[83,84], perforated peptic ulcer[83,84], haemoglobinuria[85], acute yellow atrophy[84], low plasma amylase level[86], and some cases of renal failure[21]. Thus, according to more recent data, the Cam:Ccr ratio seems to have little value in its diagnostic sensitivity and specificity for acute pancreatitis, and seems to be merely a component of non-specific tubular dysfunction similar to that found in cases of proteinuria[3,87]. However, as mentioned above, there are situations in which it might be useful to calculate the Cam:Ccr ratio such as cases of hyperlipaemic serum, macroamylasaemia, and renal failure[21,88].

Amylase and aetiology of acute pancreatitis

Generally speaking, higher amylase values have been reported in cases of acute biliary pancreatitis than in pancreatitis due to other causes[7,8,17]. Hiatt *et al.*[89] recently showed that the amylase curve profile was significantly different between alcoholic and gallstone pancreatitis. In the latter group, the initial serum amylase value was higher, the final value was lower, and the decline in daily values was more rapid. According to Gullick[90] it is probable that the magnitude of the hyperamylasaemia in pancreatitis is at least partially related to the degree of ductal obstruction and inversely proportional to the degree of acinar secretory failure. Cases of biliary disease without evidence of pancreatitis such as choledocholithiasis, cholecystitis and ruptured gallbladder[7,24,91], have occasionally been associated with high values of serum amylase, reaching up to ten times the upper reference levels. However, in these cases the absence of acute pancreatitis has rarely been demonstrated with certitude.

Alcohol is sometimes associated with asymptomatic hyperamylasaemia[92]. In some series, up to 24 per cent of chronic alcoholic patients without evidence of pancreatitis presented with an increase in serum amylase concentration[36]. Of cases of hyperamylasaemia due to alcohol consumption 44–87 per cent have been found to have a predominance of s-type isoamylase and damage to the parotid gland has often been incriminated[92,93]. On the other hand, the acute ingestion of large quantities of alcohol in non-alcoholic subjects has no effect on plasma amylase[7]. Among the numerous other substances that have been reported to induce hyperamylasaemia it is often not clear whether the amylase is of pancreatic or other origin. However, some drugs have been clearly proved to induce pancreatitis (*Table 2*).

During endoscopic retrograde cholangiopancreatography (ERCP) hyperamylasaemia was noted in 25 per cent of the cases the following morning, but only 3·5 per cent of the patients suffered from abdominal pain and fewer than 1 per cent had documented acute pancreatitis[101]. In another series, an increase in amylase levels was noted in 43 per cent of patients including 4 per cent of those with clinical evidence of acute pancreatitis[102].

In trauma, amylase determination is of little value in terms of diagnostic sensitivity or specificity[103]. An increase in serum amylase concentration is seen in approximately two-thirds of cases with blunt abdominal trauma[43,103] and is often not related to pancreatic lesions. Non-abdominal trauma including thoracic and head injury is often associated with hyperamylasaemia[43]. Isoenzyme determination does not help any further in determining the origin of hyperamylasaemia[43].

In chronic pancreatitis serum amylase concentration is usually normal during the quiescent phase[104]. An increase in both serum and urinary amylase is often seen during exacerbations, but as chronic damage progresses and pancreatic insufficiency develops, amylase elevation tends to become less pronounced and may often be in the normal range[36,104].

Amylase and prognosis of acute pancreatitis

It is commonly accepted that the level of serum amylase bears no correlation with prognosis[3,12,17,105], although it has been proposed that the level of amylasaemia could be inversely related to the severity of the disease[36,48,106]. In the experience of Albo *et al.* for instance[48], one-third of their very ill patients with haemorrhagic pancreatitis had normal serum amylase levels. Rapid destruction of acinar tissue may be associated with low amylase levels[105]. This can explain the absence of hyperamylasaemia in some cases of severe acute pancreatitis[17,106]. One of us recently showed that the severity of the disease did not appear to differ significantly in terms of Ranson's score, CT findings and clinical course when comparing patients with acute pancreatitis who had normal or elevated amylasaemia[17]. Indeed, there was even a tendency for normoamylasaemic attacks to follow a milder course.

Neither the maximal value of amylase recorded within the first 48 h following admission and during the entire hospital course, nor the variability of serum amylase, have any prognostic value regarding the evolution of acute pancreatitis[17,105]. However, persistent hyperamylasaemia, although controversial[55], is currently considered to be a good indicator of the severity of the disease[3,107]. A serum amylase level which does not return to normal levels within 5–10 days should alert the clinician to possible complications such as pseudocysts, persistent phlegmon and abscess. Ultrasonography or CT scan are indicated in such cases, also allowing a guided-needle puncture and aspiration for bacteriological study or therapeutic drainage[4].

Lipase

Lipase, an enzyme that catalyses the hydrolysis of triglycerides into diglycerides and fatty acids, does not originate exclusively from the pancreas as first believed, but also emanates from other tissues such as the liver and the stomach[71,108]. However, lipase has recently been found, with elastase-1, to represent one of the most specific enzymes in diagnosing acute pancreatitis, the value for specificity approaching 90 per cent[109]. Lipase is completely reabsorbed after glomerular filtration and is not present in the urine, although in cases of tubular dysfunction significant lipasuria has been detected[110]. Pancreatic lipase is synthesized in the exocrine acinar cells and has a molecular mass comparable with amylase; similarly it is secreted directly in its active form into the pancreatic duct as opposed to other proteases and phospholipase A which are secreted as inactive proenzymes and activated once in the intestinal lumen. In acute pancreatitis, serum lipase appears complementary to amylase, since: (1) it rises more than amylase in case of alcoholic pancreatitis compared with biliary pancreatitis[111]; (2) it remains elevated for a longer period often extending beyond 2 weeks[3,53,107,111,112]; and (3) recently, one of our studies found that about two-thirds of cases of documented acute pancreatitis without increase of serum amylase could be identified by an elevated serum lipase level[17]. Others have also emphasized the usefulness of the combination of amylase and lipase determinations[3,112]. Despite these advantages, only a few studies have used serum lipase as a diagnostic marker of acute pancreatitis[4,17,113]. This reluctance to use lipase determination could be due to the method employed for serum level determination that is turbidimetric or nephelometric assays which are not available routinely in many laboratories[3,108]. However, recently introduced rapid methods such as the lipase latex agglutination test have been shown to be very accurate and require no more than 5 min to perform[114,115]. Moller-Petersen *et al.* carried out this rapid test on 417 patients with acute abdominal pain and found only six false positive and no false negative results in the whole series[116]. This test thus appears to be very promising in unmasking normoamylasaemic pancreatitis, especially in an emergency setting. Furthermore, the systematic addition of colipase to the assay, as recommended by some authors[117], will probably enhance the accuracy of the test.

Trypsin

The pancreatic proteases (trypsin, chymotrypsin, elastase, carboxypeptidases A and B) and phospholipase A are stored in the acinar cell and are secreted as proenzymes that have a negligible catalytic activity[118–120]. Trypsin is the key enzyme for rapid activation of all these proenzymes, including its own proenzyme, trypsinogen. Natural safeguards such as pancreatic trypsin inhibitor and blood antiproteases prevent trypsin activation within the pancreatic tissue and the pancreatic juice in the ductal system until it reaches the duodenum. There, the proteolytic enzyme cascade is triggered by enterokinase[121,122].

In human subjects, trypsin and trypsinogen have been for a long time considered to be exclusively present in the pancreas, since the enzyme was undetectable after pancreatectomy[119,123]. In these conditions, serum level determination of the enzyme was thought to fulfil ideally the criterion of organ specificity[124,125]. However, trypsin has been identified by immunofluorescence in the basal cells of the crypts in the small intestinal mucosa (Paneth cells), indicating the presence of an extrapancreatic source of these proteins and a similarity between the Paneth and pancreatic acinar cells[126].

Unfortunately, trypsin in the plasma was, for a long time, not accessible to enzymatic determination since the free form is complexed to antiproteases such as α-1-proteinase inhibitor and α-2-macroglobulin (α_2M) or is present as an inactive precursor, namely trypsinogen This limitation has been overcome by the development of a radioimmunoassay specific to human trypsin[124], measuring the enzyme, its zymogen and the trypsin bound to α-1-proteinase inhibitor, but the method does not allow the differentiation of one from the other. The technique also underestimates the plasma trypsin bound to α_2M, which has less than 15 per cent immunopotency[124]. The normal serum concentration of immunoreactive-trypsin (IRT) has been reported to be anywhere between 20 μg/ml and 400 μg/ml, and this can be elevated by as much as 40 times in acute pancreatitis with a similar amount appearing in the peritoneal exudate[125,127–130]. Low levels of IRT have even been detected in cases of chronic pancreatitis, pancreatic cancer, cystic fibrosis and diabetes mellitus. Indeed increased IRT has a specificity for acute pancreatitis which is probably above 90 per cent; false positive results have been found in cases of pancreatic cancer, choledocholithiasis, chronic renal failure and following ERCP[119,120,124,125,127]. IRT remains elevated longer than amylase and is in the same time range as lipase[109,115,129] For most authors IRT does not correlate with the severity of the disease[125,128,129]; after ERCP for instance, IRT increased irrespective of pancreatic injury[127]. On the other hand, some investigators have described correlations with severity[130]; this was the case, for example, when both IRT and p3-isoamylase remained elevated[55]. Like lipase, IRT could prove useful in unmasking normoamylasaemic acute pancreatitis, but time is the major factor limiting the clinical use of trypsin, its determination by conventional radioimmunoassay takes at least 24 hours[3,51,112,114]. Recent commercially available IRT kits have been proposed which require less than 6 h to complete the assay, but they need further evaluation.

Elastase-1

Elastase-1 is also a proteolytic enzyme with specific elastolytic action and an ability to hydrolyse haemoglobin, casein, fibrin and albumin[131]. Its role in inducing major vascular lesions in acute pancreatitis was well described in 1968[132]. Until the recent development of radioimmunological methods, investigations of circulating levels of the elastase-1 have been hampered by binding with circulating inhibitors[133,134] The immunochemically detected elastase-1 in plasma corresponds to elastase-1 and α-1-proteinase inhibitor complex, since there is no free circulating elastase and the elastase-1–α_2M complex has less than 2 per cent immunoreactivity[134]. High levels of elastase-1 have been described in all cases of acute pancreatitis, in up to two-thirds of pancreatic cancer, and less frequently in chronic pancreatitis[109,133,134]. Most studies do not demonstrate any significant advantages of this enzyme when compared with amylase, lipase, and IRT in the diagnosis of acute pancreatitis, and elastase-1 levels do not allow distinction between oedematous and necrotic forms[109,112,133,135], or between alcoholic and gallstone pancreatitis[109]. The main interest in elastase-1 determination in acute pancreatitis resides in the duration and the extent of elevation of the enzyme, which were significantly greater than those of amylase, lipase and trypsin[109,112,135]. Recently, Ventrucci *et al.*[109] noted that elastase-1 was the only enzyme still elevated on the seventh day in all patients with acute pancreatitis; the mechanism of this persistent elevation is still unclear. Furthermore, elastase-1 levels seem to be less affected than other proteases by renal insufficiency[136]. Thus, considering the longer half-life of plasma elastase, this enzyme could be of value as a late marker of pancreatic injury. However, like trypsin, the clinical implication of persistent elastase-1 elevation has not yet been established.

α_2-Macroglobulin (α_2M)

α_2M, α-1-proteinase inhibitor (also known as α-1-antitrypsin) and α-2-antichymotrypsin represent, quantitatively, the most important plasma antiproteases in man[137–139]. Their main function consists in preventing the existence of free proteolytic enzymes such as trypsin and elastase[119,120,129,137–139]. α_2M is a high weight glycoprotein of about 800 000 Da present in human plasma in high concentration (about 2 mg/ml), representing most probably the key antiprotease[137–139]. After an initial limited proteolysis, α_2M undergoes a drastic change in its spatial configuration enabling it to 'entrap' and inactivate a wide variety of circulating proteases. Nevertheless, interestingly, the proteolytic activity of α_2M-protease complex towards low molecular weight substrates is not completely inhibited as is the case with parathormone, vasopressin, angiotensin, and proinsulin[137–139]; these complexes may have a role in the continuation of proteolytic activity in acute pancreatitis[120,129]. The clearance of the α_2M-protease complex is achieved by cells of the reticuloendothelial system, hepatocytes, adipocytes and fibroblasts through specific cellular receptors recognizing this complex[137–139]. However, the respective importance of these 'scavenger cells' remains unknown[137–139]. In acute pancreatitis, the site of complex formation has not been established yet[120,129]. Free α_2M has a half-life of about 100 h but is cleared within 10 min by the scavenger cells once bound to proteases[120,129].

The decreased level of α_2M has been found to be related to the severity of the clinical course of acute pancreatitis[120,125,129]. In contrast, α-1-proteinase inhibitor and α-2-antichymotrypsin levels rise along with those of C-reactive protein, since these antiproteases probably also belong to the group of acute phase proteins[129]. Furthermore, although the level of α_2M at admission hardly differs between severe and mild attacks, it seems to decrease more profoundly in the patients with severe acute pancreatitis becoming significantly depressed by 5 days after hospitalization[120,125,129]. The sensitivity of α_2M for the identification of pancreatic necrosis has recently been estimated as being close to 85 per cent; necrosis being confirmed histologically or by CT findings[135]. α_2M level does not seem to be influenced by sepsis, but low values have been reported in the case of major burns, multiple myeloma and therapy with fibrinolytic agents[140], As in acute pancreatitis, the main mechanism of the decrease of α_2M in all of these conditions seems to be a consumptive plasma depletion following protease release and clearance of formed complexes by the reticuloendothelial system.

Although a relation between the decrease of plasma α_2M and the severity of acute pancreatitis is logically conceivable, the true clinical implication is still unclear. Supplementation of plasma antiproteases with fresh frozen plasma has been suggested as therapeutic[141], but the efficacy of this treatment remains unproven[142].

Phospholipase A_2

The presence at autopsy of significant amounts of lysolecithin in necrotic tissue in fatal cases of acute pancreatitis has suggested a central role for phospholipase A_2 in the pathogenesis of the disease[143,144]. This enzyme is known to convert lecithin and cephalin in cell membranes and bile to their toxic lysocompounds[144,145], and probably also splits the alveolar phospholipids leading to the respiratory distress syndrome seen in some cases of severe acute pancreatitis[145]. The importance of phospholipase A_2 in acute pancreatitis is now supported by both experimental and clinical studies[143,144]. Phospholipase A_2 is activated by trypsin, but the latter paradoxically abolishes its activity by cleaving a bond in the amino acids of the active site on the molecule. It is probable that successive cycles of activation and inactivation in an appropriate environment in the pancreas could lead to the coagulation necrosis that is attributed to uncontrolled activity of phospholipase A_2[144]. In contrast to protease, there is no known endogenous inhibitor of phospholipase A_2. On the other hand, animal models of phospholipase A_2-induced acute pancreatitis have shown that the intraductal infusion of enzyme alone causes only mild acinar necrosis, and nearly all zymogen granules are preserved, whereas bile salts and phospholipase A_2 in combination cause extensive pancreatic necrosis, suggesting that membrane dissolution precedes hydrolysis of the constituent phospholipids[143,144]. In man, immunoreactive serum phospholipase A_2 may be elevated by as much as 500-times in acute pancreatitis, and has been found to have prognostic value[144–146], correlating especially well with pulmonary complications[145]. However, it is still unclear how much of the enzyme is of pancreatic origin[144–146]. As at least two immunologically distinct phospholipases A_2 exist in the plasma of patients with acute pancreatitis, future results should therefore be interpreted with caution[147]. Assay procedures are very difficult and time-consuming and are not yet available on a routine basis.

Ribonuclease (RNAase)

Numerous types of RNAase exist. They can be differentiated from one another by the pH of optimal activity[148]. Ten years ago, Warshaw and Lee[149], in a small series, reported that an acid RNAase of low molecular weight – resulting from the release of cell breakdown in anoxic pancreas – was an indicator of pancreatic necrosis. These authors found that 11 of 13 patients with elevated RNAase had pancreatic necrosis; and of the patients with pancreatic necrosis only one did not have an elevation of serum RNAase. However, the value of RNAase determinations is controversial. Some authors considered an early increase of the enzyme to be pathognomonic of severe acute pancreatitis[150], while others found no correlation between the clinical course and enzyme levels[151]. A rise in RNAase levels is not specific for acute pancreatitis since different clinical conditions are associated with elevations of this enzyme, namely pancreatic cancer, leukaemia, major burns, trauma, and renal failure[152]. Further investigations are needed before serial determination of RNAase can be recommended as a test for the selection of patients who will benefit from early debridement[3].

Carboxypeptidase

The digestive actions of carboxypeptidases have been widely studied, but few reports have emphasized the variation of serum levels of the enzyme in acute pancreatitis. In 1974, Fujii *et al.* reported a low activity of carboxypeptidase A in pancreatic cancer, acute and chronic pancreatitis and liver cirrhosis[153]. In acute pancreatitis, with the use of fluorimetric detection, this enzyme and its precursor were found to be more specific to the pancreas than amylase and lipase[154]. Recently, a more convenient colorimetric assay for carboxypeptidase A has been described[155]. Radioimmunoassay with antibodies specific to carboxypeptidase B has enabled detection of the active enzyme in the serum of patients with acute pancreatitis and has shown that its presence is proportional to the amount of active trypsin bound to plasma inhibitors. Thus, theoretically, carboxypeptidase B offers information on circulating levels of active pancreatic proteases, and hence on pancreatic injury[156].

Carboxylic ester hydrolase

Earlier assays were not specific enough to differentiate the two pancreatic lipolytic triglyceride hydrolysing enzymes, colipase-dependent lipase and carboxylic ester hydrolase[157]. The use of enzyme-linked immunosorbent assay (ELISA) has facilitated this distinction Carboxylic ester hydrolase, also known as cholesterol esterase, is a non-specific lipase; it hydrolyses cholesterol esters, fat-soluble vitamin esters and triglycerides[157,158]. This enzyme is also elevated in lactating mammary glands and some mammary tumours[158]. The superiority of the enzyme over current amylase or lipase determinations in the diagnosis of acute pancreatitis, as recently suggested[158], requires further investigations.

C-reactive protein

C-reactive protein is a non-specific but sensitive protein indicating tissue injury, inflammatory response, bacterial infection and ischaemic conditions[159]. It has no value in establishing the diagnosis of acute pancreatitis but may be a very sensitive indicator of pancreatic injury and useful for the follow-up of patients[135,160]. An elevation above 100 mg/l has been reported to detect 95 per cent of cases of pancreatic necrosis compared with 85 per cent for CT findings and 38 per cent for ultrasonography[135].

Methaemalbumin

Methaemalbumin results from intravascular haemolysis and is a combination of a breakdown product of haemoglobin with albumin which appears 72 h or more after the onset of acute pancreatitis[161]. The significance of methaemalbumin in the blood is controversial and its correlation with the severity of the disease[162] has not been substantiated[1,3].

Fibrinogen

Coagulation abnormalities are frequent in acute pancreatitis and can lead to severe disseminated intravascular coagulopathy. Release of trypsin as well as imbalances of proteases–antiproteases complexes have been incriminated[163] Correlations have been established between the severity of acute pancreatitis and the level of coagulation factors such as fibrinogen[163–165]. Berry *et al.*[165] suggested that a fibrinogen level greater than 6·0 g/l is a reliable predictor of future complications and equivalent to standard multifactorial prognostic tables, but this observation was not confirmed by other investigators[166].

Other laboratory tests for the future

Oxygen-derived free radicals play an important role in many diseases, especially in ischaemic disorders, causing injury to capillary endothelial cells; their role in the pathogenesis of acute pancreatitis has recently been promoted[167]. The estimation of the concentration or reactivity of these free radicals still belongs to the field of specialized laboratories.

In man, enterokinase is an enzyme strictly localized in the brush border of the enterocyte lining the duodenum and upper jejunum. The catalytically activated enterokinase could be a key triggering factor in acute pancreatitis due to pancreatico-biliary reflux[168]. Measurement of the enzyme in blood, in bile or in ascitic fluid in cases of acute pancreatitis has been suggested for future investigation. We personally doubt the potential fruitfulness of this line of enquiry because, if enterokinase is involved (and this is certainly unproven) its site of action is more likely to be intraductal rather than systemic.

Activation of trypsinogen by enterokinase in the lumen of the proximal small intestine during digestion liberates a sequence of peptides at the amino terminus of the molecule known as trypsinogen activation peptides (TAP)[169]. In physiological conditions, TAPs are probably degraded in the intestinal mucosa by proteases and oligopeptidases In the case of severe acute pancreatitis, it has been suggested that TAPs could exist within the pancreas and inappropriate release into the blood and peritoneal cavity can occur New radioimmunoassay techniques have enabled the detection of free plasma TAPs offering the means for further investigation concerning an eventual correlation between plasma level of this peptide and the severity of acute pancreatitis

The complement system undoubtedly plays a role in acute pancreatitis. The C5-peptide for instance, has been implicated as an important mediator of acute lung injury, and furthermore, it was found in the serum of patients with acute pancreatitis[170]. Plasma levels of this peptide may correlate with pulmonary complications[170].

Discussion

The major difficulty in the evaluation of acute pancreatitis through serum markers is the lack of a reliable objective diagnostic method. Acute pancreatitis can vary in its severity from a very mild disease already resolved at admission to a devastating form involving all systems and leading to death within hours. Acute pancreatitis can present as a single episode or as a series of recurrences. Efforts to create a satisfactory international classification have encountered many difficulties; it often remains unclear, for example, whether the recurrent forms should be classified under recurrent acute pancreatitis or relapse of chronic pancreatitis; this distinction has even been removed from recent classifications[171,172]. This lack of a universal definition of acute pancreatitis largely explains the discrepancies concerning the relative diagnostic value of laboratory tests and the resulting confusing opinions regarding their respective sensitivity and specificity. Another source of confusion resides in the methodology of the enzymatic level determinations and especially the variability and absence of standardization of chemical substrates used in different centres. Such laboratory subtleties can easily escape the clinician's attention, and lead to erroneous conclusions about the diagnostic efficiency of an enzyme.

Given the absence of any specific clinical signs, acute pancreatitis should be part of the differential diagnosis established for any patient admitted with abdominal pain, especially since atypical presentation is not uncommon. Systematic measurement of serum amylase, lipase or other enzymes in all cases of abdominal pain is difficult to justify, but a screening test using a urinary amylase strip (e g the Rapignost test) could be useful. This method is quite sensitive and represents an acceptable alternative to serum determinations and could alert the clinician to the possibility of acute pancreatitis. Nevertheless, as false positive and false negative results exist[76,77], complementary serum enzyme determinations are mandatory either if the test is positive or if there are clinical arguments in favour of acute pancreatitis. Total serum amylase, in spite of its sensitivity of approximately 80 per cent[17] and 70 per cent specificity[19,20], remains the most convenient laboratory test for the diagnosis of acute pancreatitis because of the simplicity and rapidity of its determination. In our opinion, the systematic association of serum amylase with serum lipase determination will eliminate most false negative and false positive results. We think that isoamylase determinations will not significantly enhance the accuracy of the combination amylase–lipase, although they could be helpful in situations of hyperamylasaemia associated with normolipasaemia. The calculation of Cam:Ccr ratio is useful only in special conditions such as hyperlipidaemic serum, macroamylasaemia and renal insufficiency.

Of the enzymatic systems other than amylase and lipase, the proleolytic enzymes deserve comment, although their diagnostic use is controversial. These enzymes are synthesized as proenzymes in zymogen granules and are activated only when secreted into the digestive tract. Pathological activation and interactions with circulating antiproteases undoubtedly play a role in the genesis of pancreatic injury. However, the exact mechanism is unclear. Progress in enzyme determination methodology is still needed in order to understand fully their role. Although their serum level determinations are not routine laboratory tests and while their assays are considerably time consuming (as opposed to those of amylase and lipase), some of these proteases seem very promising as late markers of the evolution of acute pancreatitis and may provide a valuable non-invasive assessment of the severity of the disease. For instance, IRT and elastase-1 determinations may be indicated as complementary diagnostic markers in rare cases of normoamylasaemic and normolipasaemic acute pancreatitis, especially when the delay between the onset of the symptoms and time of admission does not allow the exclusion of a return to normal values of the usual enzymatic markers. Nevertheless, we believe that in such situations the CT scan still represents a more accurate diagnostic tool[17].

The role of RNAase, phospholipase A_2, α_2M and C-reactive protein as indicators of the severity of the disease should be further investigated. With the development of simpler laboratory methods they could represent an interesting alternative to standard prognostic tables, which commonly require numerous measurements over a 48 h period[173,174]. In our opinion, these markers will allow the selection of patients who would benefit from complementary and serial CT scans and, finally, identify those requiring surgery.

Diagnostic peritoneal lavage has been advocated as a manoeuvre early in the course of acute pancreatitis. Studies of enzymes in the peritoneal fluid in acute pancreatitis have failed so far to yield convincing results, but represent an interesting alternative which certainly deserves further investigation.

Finally, we should keep in mind that in pancreatitis of alcohol origin, the peak level of most pancreatic markers is diminished due to tissue damage resulting in a reduced production capacity of the organ. Therefore, the sensitivity of laboratory tests in detecting alcohol-induced pancreatitis may remain deceptive in comparison with gallstone pancreatitis.

In conclusion, serum measurements of total amylase coupled to lipase represent to date the most practical and accurate laboratory method for diagnosing acute pancreatitis. In our opinion, other enzymatic determinations, although now often proposed in new commercial kits, should still be subject to controlled studies and systematically evaluated in terms of clinicobiochemical criteria, CT-scan findings and clinical course.

Late complications of pancreatic trauma

Pancreatic trauma is rare and experience concerning its management is consequently limited. Lessons learnt in the investigation and treatment of a group of 11 patients (median age 28·0 years, range 14–44 years), who presented with the sequelae of trauma, are described. These patients were referred to a centre with an interest in pancreatic disease at a median time of 6·0 months (range 1·5–34 months) after blunt (n = *9*) *or penetrating* (n = *2*) *injury to the pancreas. Ten of the 11 patients had undergone either single* (n = *4*) *or multiple* (n = *6*) *previous operations. Ten of the 11 patients had either strictures or disruptions of the main pancreatic duct demonstrated by endoscopic retrograde cholangiopancreatography (ERCP) and ultrasonography* (n = *8*) *or by exploration of the pancreas* (n = *2*)*. Satisfactory results were achieved by non-operative treatment in one patient and by distal pancreatectomy in eight. One further patient, who underwent distal pancreatectomy, later required completion resection because of unsuspected ductal injury in the head of the gland. The final patient continued with symptoms of pancreatitis after pancreaticoduodenectomy. It is concluded that the non-resolving sequelae of pancreatic trauma are associated with injury to the main pancreatic duct and that specialist investigation should be performed before surgical intervention is contemplated.*

Keywords: Pancreatic trauma, main pancreatic duct, endoscopic retrograde cholangiopancreatography

Pancreatic trauma is uncommon and is reported to occur in only 3–12 per cent of abdominal injuries[1]. In a recent study, Nilsson *et al.*[2] estimated that the annual incidence of pancreatic injury was 0·4 cases per 100 000 of the population examined and hence it is unusual for any individual surgeon to gain extensive experience in the management of this condition. The initial mortality rate associated with pancreatic injury remains high, up to 20 per cent in some series[3], but death is usually due to concurrent major vascular or visceral injury rather than to pancreatic trauma itself. Up to 30 per cent of survivors may develop pancreatic complications such as pseudocyst, abscess and fistula, all of which can present months or years after injury and provide considerable problems in management[4,5].

This surgical unit is a major centre for the management of pancreaticobiliary disease and deals with 50 new cases of benign pancreatic disease per annum. Over a 15-year period 11 patients have been referred with persistent symptoms following blunt or penetrating pancreatic injury. The present study reviews their previous surgical management, the types of complications and the further investigation and treatment of these patients.

Patients and methods

The case notes were reviewed of 11 patients who were referred between January 1973 and March 1988 to the Middlesex Hospital with late problems after pancreatic trauma. Particular attention was directed to the nature of any previous surgery, the types of complications at referral and the anatomy of the main pancreatic duct.

Results

There were seven male and four female patients with a median age of 28·0 years (range 14–44 years). Nine patients had originally suffered from blunt abdominal trauma and two had sustained penetrating injuries. The median time interval between the original injury and referral to The Middlesex Hospital was 6·0 months (range 1·5–34 months).

Previous surgical management

Ten of the 11 patients had undergone abdominal exploration after injury. Eight had been explored within 48 h but two others had not been explored until 2 and 3 months respectively after injury. In those eight patients who had undergone early exploration, the laparotomy findings which indicated pancreatic injury included retroperitoneal haematoma or mass in four patients, capsular tears and disruption of the pancreatic parenchyma in the two patients with penetrating trauma, and bile stained effusion with fat necrosis in one patient. The final patient had no findings suggestive of pancreatic injury. Pseudocyst was the only indication of previous pancreatic injury in those two patients who had been operated on at 2 and 3 months after injury. Associated findings included ruptured spleen (two cases), lacerated mesentery or mesocolon (two cases), fractured vertebrae (two cases), lacerated liver (one case), duodenal injury (one case) and fractured ribs (one case). Of those eight patients who were explored within 48 h of injury, five had undergone laparotomy with external abdominal drainage and three had undergone laparotomy without drainage. The two patients who underwent surgery at 2 and 3 months after injury had had cystgastrostomies performed.

Early reoperations for the development of intra-abdominal sepsis, pancreatic fistula or pseudocyst had been undertaken in six of the ten patients. Of these, four patients had had two operations, one had had three operations and one patient had undergone four operations. These procedures took the form of further external abdominal drainage only (four cases) or cystgastrostomies (two cases).

Complications at referral

Pancreatic pseudocyst was the main indication for referral in five patients and three of these had undergone previous cystgastrostomies. The other indications included recurrent acute pancreatitis with intermittent hyperamylasaemia in four patients, pancreatic fistula in one patient and pancreatic abscess in another.

Table 1 *Ductal status in 11 patients with late complications of pancreatic trauma*

Anatomy	Ductal status	Mode of presentation
	Normal	Recurrent pancreatitis (1)
	Stricture with upstream dilatation	Fistula (1), recurrent pancreatitis (1)
	Disruption with upstream dilatation	Pseudocyst (2)
	Disruption with distal end communicating with pseudocyst	Pseudocyst (1)
	Disruption only	*Pseudocyst (2), abscess (1)
	Stricture and disruption with upstream dilatation	Recurrent pancreatitis (1)
	Stricture and disruption only	*Recurrent pancreatitis (1)

The number of affected patients are given in parentheses; * includes 2 patients who were assessed at pancreatic exploration

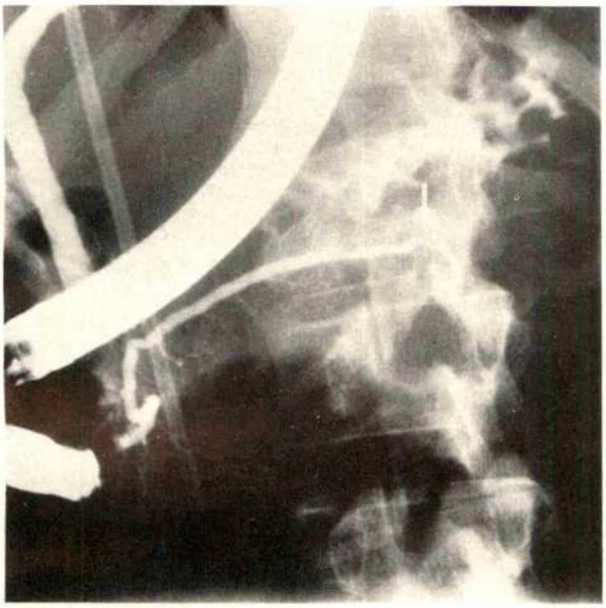

Figure 1 *Endoscopic retrograde cholangiopancreatography showing complete obstruction (arrow) of the main pancreatic duct at the junction of the body and tail of the gland*

Modes of investigation and ductal status

Nine of the 11 patients were investigated using a combination of ultrasound scanning and endoscope retrograde cholangiopancreatography (ERCP) and two of these patients also had computed tomographic (CT) scans. The two other patients, who presented in the early part of the series, did not undergo any preoperative imaging, the integrity of the main pancreatic duct being assessed at pancreatic exploration.

Ten of the 11 patients had either strictures and/or disruption of the main pancreatic duct (*Table 1*). Eight patients had injury to one region of the main duct only but two others had more than one area involved (*Table 1*). The ductal lesions were situated in the body of the pancreas (four patients), the neck (two patients), the junction of the body and tail (one patient; *Figure 1*), the junction of neck and body (one patient), the head and body (one patient) and the head and neck (one patient: *Figure 2*).

Further management

One patient with a ductal stricture in the neck of the gland and a fistula from a first order duct was treated conservatively. The fistula closed after 5 weeks of total parenteral nutrition. The remaining ten patients were managed surgically. Nine patients, eight of whom had duct injury in the neck of the gland or beyond, had a distal pancreatectomy. The ninth patient had a normal pancreatic duct but surgery was undertaken because of persistent pain and a suspected pseudocyst in the tail of the pancreas. The remaining patient who had a ductal stricture and disruption in the head and neck of the pancreas had a pancreaticoduodenectomy.

Outcome

Two patients were not followed up. One of these underwent distal pancreatectomy at the referring hospital and the other returned to her home country 1 month after operation at the Middlesex Hospital.

For the remaining nine patients the duration of follow up ranged from 2 months to 7 years. Patients were assessed for the presence or absence of abdominal pain and any change in bowel activity. Regular estimations of blood glucose level were also undertaken. The patient who underwent pancreaticoduodenectomy continued to experience pain and developed pancreatic exocrine failure. She had been referred 6 months after injury with recurrent acute pancreatitis due to stricture and disruption of the proximal pancreatic duct. The origin of her postoperative pain was thought to be chronic pancreatitis in the residual gland. One other patient, who initially underwent distal pancreatectomy, later required completion duodenum preserving pancreatectomy because of unsuspected ductal stricture in the head of the gland which produced further pancreatitis, local sepsis and stricture of the distal common bile duct. This patient was one of the two who did not undergo preoperative ERCP, ultrasound or CT scanning. Of the

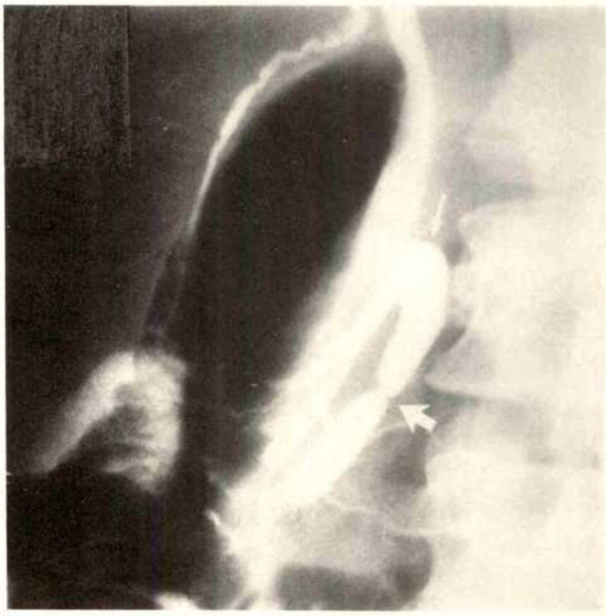

Figure 2 *Endoscopic retrograde cholangiopancreatography showing a stricture (thick arrow) and complete obstruction (thin arrow) of the main duct in the head and neck of the pancreas*

remaining seven patients, one has developed pancreatic exocrine insufficiency but there have been no instances of endocrine failure. Eight of the nine patients are pain free.

Discussion

The findings from the present study are in keeping with those of several authors who have emphasized that the operative assessment of pancreatic injury can be difficult and that significant injuries may be easily overlooked at the time of laparotomy for abdominal trauma[4–6]. Heitch *et al.*[3] and others[7] have described criteria, based on the appearance of the pancreas at operation, for assessing the severity of pancreatic injury. However, such assessment is not always reliable. The retroperitoneum may be too traumatized and obscured by haematoma to permit the detection of pancreatic capsular tears or main duct disruptions, and transections of the pancreas may be concealed beneath an intact capsule[8]. Certain authors have stressed that the identification of main pancreatic duct disruption is particularly important because such injury is associated with a high degree of postoperative morbidity unless distal pancreatic resection is performed[9–11]. This was confirmed in the present series of patients but whether extensive dissection to determine the state of the pancreatic duct should be done at the original operation is open to debate.

The contention that complications which occur months or years after pancreatic trauma can be explained on the basis of undetected duct disruption is supported by the results of specialist investigation in the present study. Pseudocysts, abscesses and fistulae are well documented sequelae of pancreatic trauma and are presumably the result of continued leakage of pancreatic enzymes from a disrupted ductal system which has failed to heal following injury[4,8]. By contrast, recurrent acute pancreatitis due to ductal stricture is less well recognized but it occurred in three of our patients. It seems likely that incomplete duct transection may subsequently heal by fibrosis with stricture formation.

Although the classical site of pancreatic duct injury lies over the vertebral column[4,12], it is clear from this series that disruptions of the duct can occur in any of the anatomical subdivisions of the gland. It has been noted that more than one region may be involved[9] and our data support this observation. As demonstrated by one patient in the present study, these findings carry important practical implications because strictures or disruptions may remain undetected unless imaging is undertaken before definitive surgery.

Accurate diagnosis of main duct disruption soon after injury would be of value in the prevention of the delayed sequelae of pancreatic trauma described in this and other studies[4,9,13]. Sugawa and Lucas[14] have recently drawn attention to the role of ERCP in the early evaluation of pancreatic trauma and Barkin *et al.*[15] correctly identified duct disruptions in four of 14 patients with suspected pancreatic trauma who underwent ERCP within 72 h of injury. ERCP represents a major advance in the assessment of the injured pancreas. In patients with suspected pancreatic trauma, who do not require immediate operation for concommitant life threatening injury, ERCP should be undertaken to define the nature of the trauma more clearly.

On the other hand, in those patients who do require immediate surgery after abdominal trauma and in whom main pancreatic disruption is suspected but not confirmed following gentle exploration of the pancreas, we support the opinion of Hendel and Rusnak[9] that careful external drainage provides an acceptable and preferable alternative to blind pancreatic resection. In the event of pancreatic complications, specialist assessment of the pancreas by a combination of ultrasound, CT scanning and ERCP should be undertaken to determine the extent of the disease and the status of the duct. In this way a sensible definitive procedure can be planned to minimize the risk of further complications or late recurrence of pancreatic disease.

Intravenous digital subtraction angiography is relatively hazardous and inaccurate. It appears from the literature to have little place in either the screening of patients with putative carotid artery disease or in the assessment of those about to undergo carotid endarterectomy.

Keywords: Digital subtraction angiography, extracranial carotid artery disease

Radiologists perform angiograms but the decision to do an angiogram generally rests with the surgeon and a knowledge of the benefits and drawbacks of angiography is, therefore, of considerable importance in surgical practice. Such knowledge is especially relevant in the field of extracranial cerebrovascular disease for which angiography has well recognized hazards and for which other techniques, notably ultrasonography, compete for the position of most useful investigative technique. Although the place of carotid endarterectomy remains to be defined completely[1,2], it is widely advocated for patients with carotid territory transient ischaemic attacks due to extracranial carotid artery disease. The operation is usually preceded by angiography to demonstrate the site and morphology of the stenosis to be removed[3], and it has been suggested that when perioperative stroke occurs in less than 3 per cent of patients, stroke incidence may be reduced in the long term, compared with the natural history of the untreated disease[1,2,4]. However, conventional angiography of the carotid artery may itself provoke a major stroke in as many as 2·4 per cent of patients[5] and it is principally this risk which has prompted the search for safer techniques of diagnosing extracranial carotid artery disease.

One such technique is intravenous digital subtraction angiography (IVDSA)[6–10], and early reports suggested that in many instances IVDSA might replace conventional angiography[11–15], especially in terms of screening patients for carotid artery disease[16,17]. This early promise seems not to have been realized[18,19] and, indeed, it has become clear that the complications of the technique may pose a greater problem than was initially anticipated[20]. Furthermore, major concern has been voiced in some quarters over the difficulty in obtaining images on a regular basis that are of comparable quality to those obtained with conventional angiography, and the factors that limit image quality have been described[21]. Another problem, particularly when IVDSA is used for screening purposes, is that the negative predictive value of a normal IVDSA result is low[22], which implies that significant stenoses may be overlooked. With this background, we have examined the current value of IVDSA, as outlined in the literature, by assessing two features of the technique, namely risk and accuracy. To eliminate any bias inherent in retrospective analyses we have considered only prospective data. In addition, we have included reports of the use of IVDSA only in suspected extracranial carotid artery disease because of evidence suggesting that the risk of carotid angiography varies with different pathologies[23]. When considering the accuracy of IVDSA, we have assessed both its ability to measure the absolute degree of stenosis and its ability to differentiate between haemodynamically significant and haemodynamically insignificant lesions.

Definition of complications

Only two prospective studies are available which fully describe the complications of IVDSA[24,25]. The occurrence of two groups of complications was recognized, namely major systemic complications, such as myocardial infarction and pulmonary oedema, and neurological complications. The latter were subdivided into transient ischaemic attacks in which the neurological deficit resolved totally within 24 h of angiography, minor stroke (resolution within 7 days) and major stroke (resolution after 7 days or no resolution)[5].

Definition of accuracy

The accuracy of a particular patient's investigation was assessed by comparing the estimated degree of stenosis of the internal carotid artery on IVDSA with that on conventional angiography or with that obtained by direct measurement at endarterectomy. Based on the grading of stenosis of Chilcote *et al.*[26], who used categories from zero to 100 per cent in increments of 20 per cent, we considered that a given result using IVDSA was accurate when the grade of stenosis as judged by this method and conventional angiography was the same; any discrepancy was considered to represent an inaccurate study. This differs from the definition of 'accurate' used by Chilcote *et al.*[26] and Russell *et al.*[27] who regarded as accurate a result using IVDSA that was within one grade either side of the conventional angiographic grade. Such a definition obviously increases the apparent accuracy of IVDSA: for instance, it allows stenosis measurements of both 21 and 80 per cent to be regarded as in agreement with any conventional angiographic measurement between 41 and 60 per cent. Because 'agreement' could represent a difference of up to 39 per cent between the stenosis observed from IVDSA and from conventional angiography for any given patient using the grades of Chilcote *et al.*, we believe that our more stringent definition is more relevant to clinical practice. This alteration in definition accounts for the discrepancy between the accuracy of IVDSA reported by the original authors and the re-evaluated accuracy reported here.

The accuracy of IVDSA in any series was first of all taken as the ratio, expressed as a percentage, of the number of accurate studies (where both methods agreed) to the total number of arteries examined by both techniques. This is complicated by the fact that not all IVDSA examinations were technically adequate and that both the definition of an inadequate study and the details of such studies were described differently by different authors. Clearly, if inadequate studies are not considered, the apparent accuracy of IVDSA in a series rises. To allow for this we have considered, unless specific contrary information was presented, that 'uninterpretable', 'poor' or

* Derived value

'non-diagnostic' studies were for present purposes inaccurate. In one paper the absolute number of inadequate studies using IVDSA in the subgroup of patients also undergoing conventional angiography was not reported[28], but this could be estimated using the reported overall incidence (7 per cent) of unsatisfactory studies using IVDSA. We have, as a secondary consideration, also estimated the accuracy of 'adequate' studies by excluding the inadequate studies, although this estimation is less reliable because of author variation in the definition of a poor study.

The accuracy of IVDSA in determining the presence or absence of a lesion of haemodynamic significance was also estimated. This was hampered by variation in the boundaries of grades of stenosis described by various authors, so, depending on the series, a haemodynamically significant lesion has been taken variously as one of stenosis greater than 60, 70 or 75 per cent diameter. IVDSA was considered accurate in this respect if it agreed with conventional angiography on the presence or absence of a lesion of the appropriate 'haemodynamic' severity, according to the grading system of the relevant paper.

Complications

The result of the two studies which detail complications are shown in *Table 1*. In one study, IVDSA in 102 patients caused one major stroke, two transient ischaemic attacks and 23 major systemic complications, including one cardiac arrest and probably two myocardial infarctions. In the other study of 500 patients there was one major stroke, one transient ischaemic attack and 32 major systemic complications. These data suggest a 0·3 per cent risk of major stroke, a 0·5 per cent risk of transient ischaemic attack and a 9·1 per cent risk of major systemic complication for IVDSA when assessing extracranial carotid artery disease.

Accuracy

Four prospective studies comparing IVDSA with conventional angiography or the appropriate operative specimen were identified[26–29]. Chilcote *et al.*[26] included full details of all interpretable studies. Two studies which were uninterpretable because of power injector failure were not considered to be specifically failures of IVDSA and were excluded. The remaining uninterpretable studies were considered inaccurate for the purposes of the present analysis[26]. Russell *et al.*[27] also give full details of all interpretable studies. We considered their remaining uninterpretable studies to be inaccurate. Wood *et al.*[28] give full details of interpretable studies, but, as described above, the number of uninterpretable studies has been derived using their overall figure for uninterpretable IVDSA (7 per cent). Reilly *et al.*[29] used the relevant endarterectomy specimen as the standard against which IVDSA was assessed. They report the accuracy of IVDSA in patients with adequate and inadequate studies without using grades of stenosis, which means that their data cannot be used in assessing the accuracy of IVDSA with regard to lesions of haemodynamic significance.

Prospective data comparing IVDSA with conventional angiography also exist in studies comparing both IVDSA and ultrasonography with conventional angiography. Five such studies were identified[30–34], of which two were considered unsuitable for inclusion here. D'Alotto *et al.*[30] present their results in such a way that the data required by the present study are inaccessible, and Zweibel *et al.*[31] do not distinguish between details of internal carotid evaluation and those of external carotid studies. Although Mendel *et al.*[32] compared IVDSA with conventional angiography in only 14 vessels, they give full details. Glover *et al.*[33] also give full details of all vessels evaluated with both conventional angiography and a technically adequate IVDSA, although not of the number of

Table 3 *Accuracy of intravenous digital subtraction angiography related to haemodynamically significant lesions*

Author (year)	Significant lesion (%)	Accurately ascribed significant lesion	Accurately ascribed insignificant lesion	Total accurately ascribed lesions	Total all studies	Accuracy (%)

inadequate studies using IVDSA. Their incidence of inadequate studies using IVDSA overall (10 per cent) is used to estimate the number of inadequate studies in patients who also had conventional angiography. Turnipseed *et al.*[34] present full details of all studies.

Table 2 shows data relating to the overall accuracy of IVDSA at determining internal carotid stenosis. The series combine to give an overall accuracy of 64 per cent. If only technically satisfactory examinations are included, the figure rises to 73 per cent. *Table 3* shows that the accuracy of IVDSA at detecting haemodynamically significant lesions is 85 per cent.

Discussion

Reviewing IVDSA in 1985, Sumner *et al.*[35] noted 'no strokes or serious neurological events' from the technique. In 1989 it is now clear, even from the limited number of prospective studies available to us, that IVDSA for extracranial carotid disease does carry some risk of stroke as well as a pronounced risk of major systemic complications. These systemic complications offset the benefit of a reduced stroke risk when IVDSA is compared with conventional angiography. Broadly speaking, the risk attached to IVDSA, although rather different in nature, is not appreciably less than that from conventional angiography. Even if the accuracy element is ignored, the problem of complications alone should rule out IVDSA as a screening procedure for patients with putative extracranial carotid artery disease. When the apparent accuracy is also considered, the technique in most centres seems to be unequal to the task of usefully delineating disease in the carotid artery before carotid endarterectomy.

The attraction of IVDSA for screening purposes becomes even less when one considers the relative success of ultrasonography, a safe and much less expensive option, in this context[36]. Some authors have even suggested that clinical examination combined with ultrasonography may not only identify candidates for operation but that ultrasonography may also adequately outline the extent of the arterial disease for the surgeon, making angiography of any kind unnecessary[37]. Duplex scanning is undoubtedly the most popular ultrasound technique in this respect[38] and even those who have believed duplex scanning and IVDSA to be comparable have preferred the former on grounds of cost efficiency, speed and repeatability[39]. Others have found duplex scanning to be comparable to conventional angiography, still the gold standard for most people, in a prospective study. The ultrasound technique in good hands may be just as accurate as conventional angiography in assessing stenosis and even more useful in assessing plaque characteristics[40].

In conclusion, there would seem at this time to be adequate evidence in the literature to show that IVDSA is relatively hazardous and inaccurate in most centres. It would seem to have little place in either the screening of patients with possible extracranial carotid artery disease or in pre-endarterectomy assessment. It may be that digital subtraction technology is better reserved for use with 'conventional' intra-arterial injection of contrast agent[41–43].

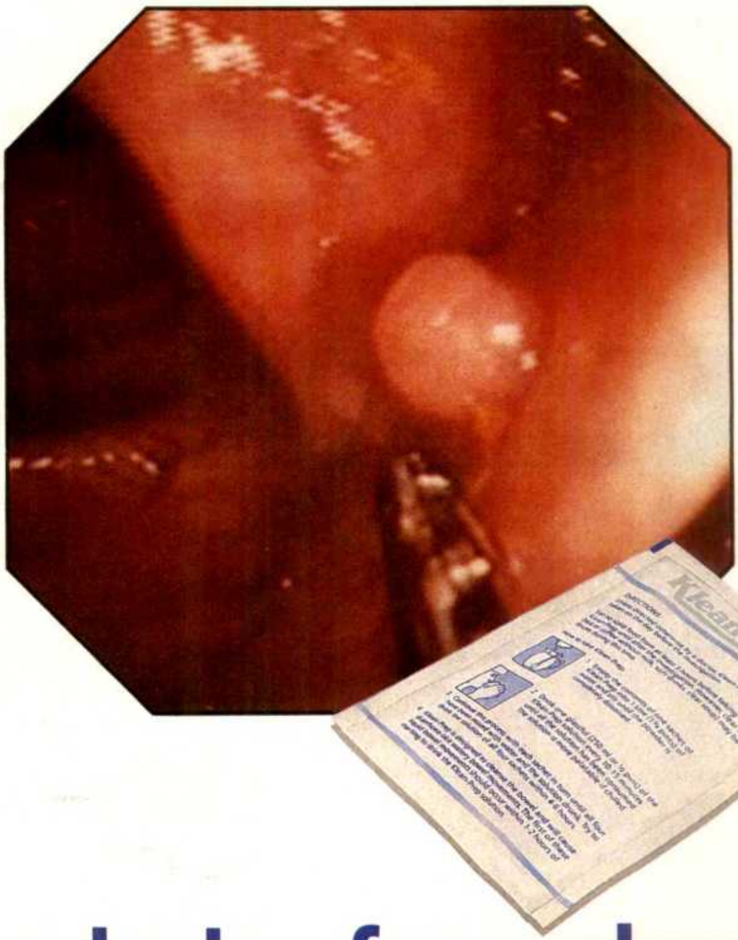
Klean·Prep*

Polyethylene glycol 3350, sodium sulphate, sodium bicarbonate, sodium chloride, potassium chloride



Today's choice for a clean colon

for colonoscopy, colonic surgery, barium enema

- **Bowel cleansing** Superior bowel cleansing to standard regimens (1,2).
- **Safety** Negligible water and electrolyte disturbance (3).
- **Well tolerated** (1,2,4) Pleasantly flavoured.
- **Economy** Shortens preoperative stay (1,2,4).

Abbreviated Prescribing Information: Presentation: An off-white powder, packed in 4 sachets. Each sachet contains: Polyethylene Glycol 3350 59.00g, Sodium Sulphate 5.685g, Sodium Bicarbonate 1.685g, Sodium Chloride 1.465g, Potassium Chloride 0.7425g. **Uses:** Bowel preparation before colonoscopy, colonic surgery, radiological examination and other related procedures. **Dosage and Administration:** Reconstituted solution for oral administration. *Adults (including the elderly):* The contents of one sachet to be dissolved in 1 litre of water. 250ml to be drunk rapidly every 10-15 minutes until all the solution has been consumed. The procedure to be repeated with all four sachets or until the rectal effluent is clear. The solution from all 4 sachets should be drunk within 4-6 hours. No dosage changes need be made for patients with renal insufficiency. If administered by nasogastric tube the rate of administration should be 20-30ml/minute. *Children:* Not recommended. **Contra-indications, Warnings etc.** *Contra-indications:* Gastro-intestinal obstruction or perforation, ileus, gastric retention, acute intestinal or gastric ulceration, toxic colitis or megacolon. Patients with body weight less than 20kg. *Warnings:* Extra care should be taken in patients with impaired gag reflex, reflux oesophagitis, those with diminished levels of consciousness and in ulcerative colitis. *Interactions:* All oral medications should be given at least 1 hour prior to administration. *Side-effects:* Nausea, abdominal fullness, bloating may be experienced. Abdominal cramps, vomiting and anal irritation occur less frequently. These effects normally subside rapidly. Urticaria and allergic reactions have been reported rarely. Should distension or pain arise the rate of administration may be slowed. *Use in Pregnancy:* Careful consideration should be given before use in pregnancy. **Precautions:** The reconstituted solution should be refrigerated and used within 24 hours. Any unused portion should be discarded. **Package quantity:** Unit dose pack of 4 sachets. **Basic NHS price:** £8.60. PL 5628/0003 Licence holder: Birex Pharmaceuticals Ltd. Further information is available from Norgine Limited. *Klean-Prep is a trademark.

Vascular Surgery Unit, Royal
Infirmary, Lauriston Place,
Edinburgh EH3 9YN, UK
Correspondence to:
Mr a. McL. Jenkins

Between 1978 and 1987, 587 cases of abdominal aortic aneurysm were operated on in the Vascular Unit of the Royal Infirmary of Edinburgh. Over this ten-year period there was a dramatic increase in the number of patients treated. Rupture had occurred in 278 patients. Of the 309 patients with non-ruptured aneurysm 175 were asymptomatic, 84 were symptomatic and 50 were acutely symptomatic. Two hundred and fifty-nine patients underwent elective operation and the 50 acutely symptomatic patients were operated on as emergencies. The overall mortality for the non-ruptured series was 2·9 per cent. The mortality in patients undergoing elective surgery was 1·9 per cent (1·1 per cent in asymptomatic and 3·6 per cent in symptomatic patients) and 4·0 per cent for patients undergoing emergency surgery.

Keywords: Non-ruptured aortic aneurysm

Recorded deaths from abdominal aortic aneurysm in England and Wales have shown a progressive and linear increase over the past 30 years[1]. They now account for 1·7 per cent of all deaths in men aged 65–75 years and show a particular increase in elderly women[2]. Without surgery the mortality for patients presenting with ruptured abdominal aortic aneurysm approaches 100 per cent[3]. In those who are operated upon following rupture, mortality rates of 40–60 per cent have been reported[3,4] and these can be improved in a specialized unit[5].

It has been suggested that the survival of patients with abdominal aortic aneurysm could be improved by early detection, appropriate selection and elective aneurysm repair before rupture supervenes. This depends upon an acceptable operative mortality being achieved. The purpose of the present study was to evaluate the outcome of operations for non-ruptured aneurysms of the abdominal aorta carried out over a ten-year period.

Patients and methods

The patients included in this study comprised all those with non-ruptured aneurysm of the abdominal aorta operated on in the Royal Infirmary of Edinburgh during the period January 1978–December 1987. The Vascular Surgery Unit of the Royal Infirmary of Edinburgh was formally established in 1982, before which the surgeons worked in separate general units. Approximately 85 per cent of referrals came from the Lothians area and the remainder from adjacent Health Board areas. The overall catchment population is approximately 1·2 million.

Patients with aneurysms of the thoracic aorta, aortic dissection, acute thrombosis, frank rupture or evidence of blood outside the aortic lumen were excluded from the analysis and the remainder allocated to one of three groups. (1) elective asymptomatic – patients admitted non-urgently, without signs or symptoms referrable to the aneurysm, for planned elective surgery; (2) elective symptomatic – patients admitted non-urgently or as emergencies, with symptoms referrable to their aneurysm but without evidence of rupture and not deemed to require urgent exploration; (3) acute symptomatic – patients admitted as emergencies without signs of rupture but with sufficient symptoms or signs to merit urgent exploration within 24 h of admission. Subsequent operation showed there had been no leakage of blood outside the aortic lumen in these patients.

The data were obtained from unit statistics assembled annually for the Lothian Surgical Audit and checked against operation books and individual case records.

During the study period the vast majority of patients were assessed preoperatively by one of two consultant anaesthetists. Patients who had been judged to have significant risk factors, e.g ischaemic heart disease, systemic arterial hypertension or chronic respiratory disease, were admitted well in advance of surgery. Hypertension and poor respiratory function were improved by drug therapy and/or physiotherapy. Patients with a history of heart disease (myocardial infarction, left ventricular failure, or electrocardiograpic evidence of infarction or ischaemia or left ventricular hypertrophy) were either cardiologically assessed or, in recent years (1985–87), submitted to formal radionuclide ventriculography to obtain a value for left ventricular ejection fraction (LVEF) as an assessment of left ventricular function. Those with an LVEF >40 per cent were operated on with direct arterial and central venous pressure monitoring. Patients considered to be at risk of rupture who had surgery despite an LVEF between 30 and 40 per cent had pulmonary artery pressure monitoring via a Swan-Ganz catheter. Patients with small asymptomatic aneurysms and an LVEF <30 per cent had their operation deferred.

Antibiotic prophylaxis was used in every case, beginning either 24 h preoperatively or peroperatively, and continued for 4 days. The majority of patients were anaesthetized by one of two consultants or by a senior registrar who was directly supervised by one of the consultants All operations were performed or directly supervised by a consultant vascular surgeon. Eighty-six per cent of the patients in the second half of the study period received combined low thoracic extradural and general anaesthesia, the extradural anaesthesia being continued by an infusion for up to 36 h postoperatively. This technique offered excellent stability of arterial blood pressure, lower limb vasodilation and wound analgesia. After surgery the patients were managed, breathing spontaneously, in the vascular ward using continous direct cardiovascular monitoring and constant high dependency nursing supervision for up to 24 h. No specific prophylaxis against acute renal failure was used routinely, other than appropriate circulatory filling with blood, crystalloid and colloid according to need Patients were electively admitted to the intensive care unit when postoperative ventilation was required, usually for significant respiratory disease, and on the rare occasions when pulmonary artery pressure was being monitored

Results

Three hundred and nine patients underwent operation for non-ruptured aneurysm in the 10-year study period. A striking progressive increase in the number of patients operated on is shown (*Figure 1*) which mirrors an increasing referral rate for ruptured aortic aneurysm[5]. Ninety-one operations were performed in the first half and 218 in the second half of this period. The age and sex distribution of patients is shown in *Figure 2*, the mean age being 68 years (range 43–84) and the male:female ratio 4:1.

Two hundred and fifty-nine operations were performed electively, of which 175 were for asymptomatic and 84 for symptomatic aneurysms. Fifty patients had emergency procedures for symptomatic aneurysms.

Aneurysm dimensions were established by ultrasound, computed tomography or intraoperative measurement, the mean maximum transverse diameter being 6·4 cm (range 3·2–15·0 cm). No significant difference in the composition of the clinical groups with regard to aneurysm size was noted.

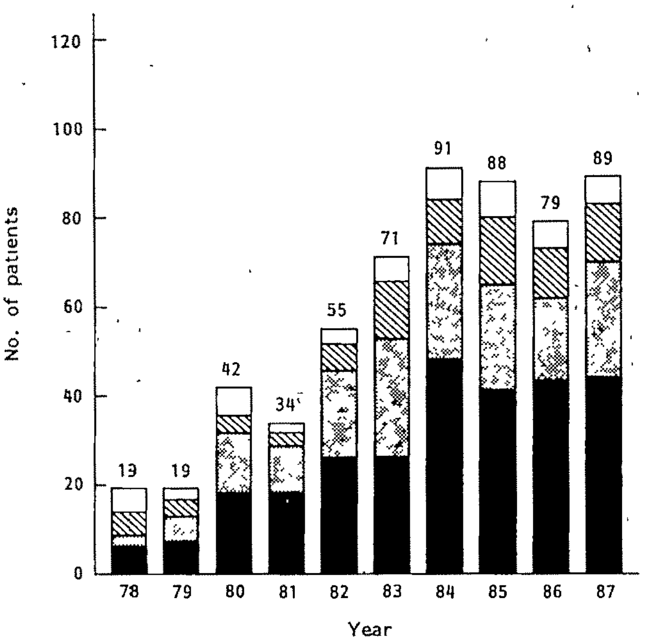

Figure 1 *Number of aneurysm operations for the years 1978–87.* ■, *Rupture;* □, *asymptomatic;* ■, *elective symptomatic,* □, *acute symptomatic*

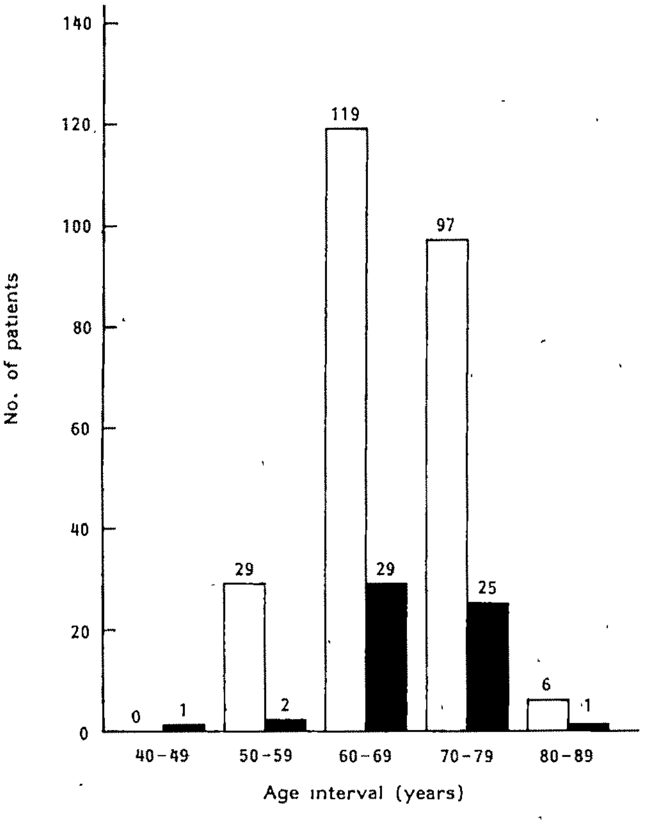

Figure 2 *Age and sex distribution of 309 patients with non-ruptured aneurysms.* □, *Men,* ■, *women*

The aneurysm extended above the renal arteries in only four patients and was confined to the infrarenal aorta in 97·5 per cent of cases. The iliac arteries were aneurysmal in 85 patients (27 per cent).

Fourteen aneurysms were diagnosed as inflammatory of which ten were symptomatic Of the 134 patients with symptomatic aneurysms, 63 per cent presented with abdominal pain, 34 per cent with back pain, 6 per cent with limb pain and 2 per cent with limb paresis.

Symptoms indicative of occlusive peripheral arterial disease were seen in 19 per cent of patients. Aortography to assess the proximal extent of the aneurysm and the distal circulation was performed in 31 patients, nine of whom were found to have additional peripheral aneurysms, five femoral and four popliteal.

Operations and grafts (Table 1)

In 76 per cent of patients a transverse incision was used, a vertical incision in 21 per cent and a paramedian in 3 per cent. All patients had a laparotomy, but in seven no graft was inserted. One hundred and ninety-three patients (62 per cent) received bifurcation grafts and 109 (35 per cent) received tube grafts. Six patients also had renal revascularization procedures for correction of renovascular hypertension or preservation of renal function. In two of these patients, in whom the aneurysm extended above the renal arteries, a kidney was temporarily removed and cooled. After the insertion of a Dacron® tube graft (du Pont), the kidney was transplanted to the iliac fossa. Of the seven patients who did not have a graft inserted, two had aneurysms extending well above the renal arteries, three had difficult access to the aorta owing to dense adhesions from previous surgery, one patient with acute symptoms had intestinal infarction and one patient died from an intraoperative myocardial infarction before insertion of the graft. After operation 65 per cent of patients were returned directly to the vascular ward (with high dependency nursing care) and 35 per cent were managed on an intensive care unit. Twenty-three patients underwent a second operation during the same admission, ten for control of intra-abdominal or wound bleeding, two for ischaemic colon, five for insertion of a Teflon®-Silastic® arteriovenous shunt for haemodialysis and six for lower limb ischaemia (graft thrombectomy, femoral embolectomy, refashioning of one limb of a bifurcation graft, popliteal thrombectomy and a femoropopliteal crossover graft), with no resultant amputations.

Outcome (Table 2)

Nine patients died within 30 days of operation, seven following the successful insertion of a vascular prosthesis and two following laparotomy without aortic replacement. The cause of death in those patients receiving a graft is shown in *Table 3*. No inpatient deaths occurred after 30 days.

One hundred and six patients made an uneventful recovery following operation. In the remainder, frequent causes of postoperative morbidity included chest infection, myocardial infarction, congestive cardiac failure and renal failure (*Table 4*).

The mean hospital stay for patients undergoing aortic reconstruction was 12 days, 30 per cent requiring additional convalescent care.

Aneurysm bacteriology

Twenty positive cultures were obtained from the 200 patients who had samples taken from within the aortic sac. Organisms

Table 1 *Nature of operation*

Operation	Number of patients
Tube graft	109 (35)
Bifurcation graft	193 (62)
Aortobi-iliac	137 (44)

included *Staphylococcus aureus* and *Staphylococcus albus*, *Escherichia coli*, *Streptococcus viridans*, *Clostridium perfringens* and *Bacteroides fragilis*. No evidence of graft infection was seen during the early postoperative period and, in the two patients who died of sepsis, organisms isolated from blood cultures showed no relationship to those previously isolated from the aorta.

Discussion

The natural history of unoperated abdominal aortic aneurysm is difficult to establish and most studies to date have been retrospective[6,7]. Szilagyi *et al.* showed that 43 per cent of patients who did not have surgery because of severe coexistent disease subsequently succumbed from rupture of their aneurysm[7]. Aneurysms are reported to grow at approximately 0·5 cm per annum[8] and the risk of rupture increases as the aneurysm enlarges. Patients generally become less fit with advancing age, a further factor which favours early elective surgery. Nevertheless, such surgery can only be justified if the risk of death or disability from operation is small.

Evidence continues to accumulate that abdominal aortic aneurysm is an increasing problem[9,10] and that the mortality from this condition, if calculated from hospital data, is likely to be grossly underestimated. A recent large Swedish post mortem study suggested that mortality may be as high as 94 per cent if deaths in the community are included[11].

It is difficult to identify objectively the particular factors contributing to the improved outcome for this condition in our unit. In other centres, improved results of elective aneurysm surgery have been accredited to careful selection of patients, based on cardiac function assessed by radionuclide angiography[12] or dipyridamole thallium scanning[13]. While we have not routinely measured ejection fraction on all patients, such measurements have been applied selectively in patients with clinical evidence of significant cardiac dysfunction. All patients undergoing either elective or emergency aneurysm surgery were monitored by arterial pressure line, central venous pressure line and infrequently by Swan-Ganz catheter. This policy may in part be responsible for our survival results and may be compared with the experience of Whittemore *et al.*[14] who routinely monitored Swan-Ganz catheter pressures in patients undergoing such surgery. Several authors[15,16] have suggested that the use of a greater proportion of tube grafts can reduce mortality and it is worthy of note that Makin[15] used tube grafts in 84 per cent of his cases. In contrast, we have used tube grafts for aortic replacement in only 35 per cent of cases. This may reflect a lower threshold for the insertion of a bifurcation graft, which in our hands has not been associated with a significantly different blood loss or mortality. It is frequently technically easier to insert a bifurcation graft into the iliac arteries than to struggle with calcified atheroma at a lower aortic anastomosis. Finally, it has been suggested that prior coronary artery bypass grafting in appropriate cases can protect patients from postoperative myocardial infarction and thereby improve mortality rate[17]. In the present series, no patient underwent prior coronary bypass grafting.

The present study confirms the rising surgical workload from aortic aneurysm. The age and sex distribution and incidence of intercurrent disease was similar to that in other published series. The operative mortality for elective surgery was 1·9 per cent and that for emergency repair of symptomatic aneurysms was 4·0 per cent which compares favourably with most reported series (*Table 5*) and is in stark contrast to the results for ruptured aneurysm, which in this unit has averaged 28 per cent over the past 5 years[5]. The low mortality and morbidity herein reported lends further support to a policy of elective repair of abdominal aortic aneurysm before rupture ensues. However, despite increased awareness of the disease, approximately one-third of all patients admitted with rupture remain undiagnosed until the event[21].

Life expectancy following repair of abdominal aortic aneurysm is similar to that of matched population controls[22]. Even in 80-year-old patients a reasonable improvement in life expectancy can be expected assuming even the least favourable

Table 2 *Operative mortality*

Group	Number of patients	Number of deaths
Overall	309	9 (2·9)
After insertion of graft	302	7 (2·3)
Elective operation	259	5 (1·9)
asymptomatic	175	2 (1·1)
symptomatic	84	3 (3·6)
Emergency operation	50	2 (4·0)

Values in parentheses are percentages

variables in regard to elective surgery[1]. Furthermore, Bowers and Cave[23], using actuarial analysis in a defined closed community, have shown elective surgery to produce a 40 per cent improvement in observed 5-year survival of patients with abdominal aortic aneurysms when compared with either conservative management or surgery following rupture. This provides additional support for a policy of elective repair. A long-term follow-up study of this series of patients is currently underway.

A total of 112 first ribs in 103 patients were resected over 11 years for thoracic outlet syndrome. Seventy-seven patients (84 operations) were followed up for 2·5 years or more to assess the long term results of this procedure and the factors affecting them. One month after surgery 52 per cent of limbs were asymptomatic and 77 per cent were at least improved. A follow-up examination was performed, on average 6·1 years after the operation, by two independent examiners. This evaluation showed a permanent success rate of 37 per cent among 84 limbs examined. These long term results compare unfavourably with previously published data. The reason for the poor final outcome seemed to be difficulty in selecting patients for the operation. This was not aided by any of the preoperative tests. Patients in this study were evaluated by independent examiners, and only a total absence of preceding symptoms was accepted as the criterion for success. We emphasize the importance of unbiased evaluation and long term follow-up.

Keywords: Thoracic outlet syndrome, first rib resection, observer bias

Thoracic outlet syndrome (TOS) is a symptom complex caused by compression of neurovascular structures as they leave the thoracic cage through its narrow upper aperture. The first rib is generally responsible for this compression since scalenotomy does not produce permanent relief[1,2]. The operation of choice is the transaxillary removal[3] of the first rib, fibromuscular bands and cervical rib, when present[4] Many surgeons using this method have reported good to excellent primary results in between 80 and 99 per cent of patients[2–15] Failure to obtain the anticipated relief after resection of the first rib is usually due to inaccurate diagnosis and, consequently, inappropriate surgery[16]. Assessment problems also occur after surgery because no objective method is available for the evaluation of outcome[17]. The aim of the present study was to evaluate the long term outcome after resection of the first rib. A follow-up study was done 2·5 to 13·5 years after first rib resection by performing a thorough clinical evaluation and cervical X-ray examination. To minimize observer bias this was done by two independent investigators.

Patients and methods

A total of 112 first rib resections was carried out on 103 consecutive patients in the Fourth Department of Surgery, Helsinki University Central Hospital during an 11-year study period up to the end of 1985 The mean age of the patients was 37 years (range 19–61 years) and the female·male ratio was 58:45. All patients were initially examined by a vascular surgeon. A cardiologist, a neurologist and an orthopaedic surgeon were consulted in selected cases Positional provocation in a vascular laboratory, functional angiography and electroneuromyography were subsequently performed in 33 patients during the first years of the study The decision to resect the first rib was largely based on clinical judgement with emphasis on a typical history and the exclusion of other potential causes of radiculopathy. A transaxillary approach was always used for the resection of the first rib, which was performed extraperiosteally in all but the first 17 patients. Patients were usually discharged on the third or fourth postoperative day and were advised neither to raise the arm above the shoulder for 4 weeks nor to use it for lifting or exertion. The surgeon carried out a routine examination about a month after operation and patients were then usually allowed to return to work without restrictions

The long term follow-up examination was made on average 6 1 years (range 2·5–13 5 years) after operation None of the surgeons involved in the preoperative examination, selection of patients, surgery, or early postoperative follow-up participated in the long term follow-up examination A questionnaire was sent to the patients 1 month before this examination. Two independent examiners, consultants in neurology and in physical medicine and rehabilitation respectively, from another university hospital undertook this clinical examination, which lasted 30 min or more, and at which data were simultaneously recorded by two nurses.

The examination comprised systematic assessment of the movements and mobility of the cervical spine, shoulder girdles, elbows, wrists and hands Sensory modalities and reflexes of the upper arms were also tested In addition to the classical TOS provocation tests, Adson's, Wright's and Eden's tests, Roos's exercise test was also performed. Both subclavian arteries were auscultated and distal pulses palpated Status was defined as abnormal if there were definite abnormal findings in either the active or passive movements tested or in the muscle and nerve functions tested The cervical spine was radiologically examined to assess the stump of the first rib.

The association of various pre- and postoperative factors with postoperative outcome was retrospectively assessed The value of preoperative tests in terms of different outcome was assessed using the χ^2 test or Fisher's exact test as appropriate

Results

During follow-up three patients died from causes unrelated to TOS. Of the remaining 100 patients with 108 resected first ribs, 77 with 84 resected ribs attended the follow-up examination.

At the 1-month postoperative examination, preoperative symptoms were found to be reduced in 83 (77 per cent) of 108 limbs, with 56 (52 per cent) of limbs totally asymptomatic. At long term follow-up, 31 (37 per cent) of 84 limbs remained asymptomatic. In one patient the vascular clamps used for controlling profuse bleeding had caused permanent damage to the brachial plexus. Two others had developed sequelae to venous thrombosis A further 23 (27 per cent) limbs had hypoaesthesia or dysaesthesia of the inner aspect of the upper arm due to an intercostobrachial nerve lesion.

If symptoms had been provoked preoperatively by work, had been at their worst during the night, had been associated with neck pain or had previously led to scalenotomy, the first rib resection was more often unsuccessful than in patients without such associations (*Table 1*). There was no difference between the patients with long term success and those with remaining symptoms in terms of age or duration of symptoms The mean age at operation was 38 years (range 24–61 years) in the successful group and 37 years (range 19–54 years) in the

Adson's, Eden's or Wright's test	87	86

group with residual symptoms. Duration of TOS was 24 months (range 3–52 months) and 31 months (range 4–132 months) respectively. Preoperative tests performed on selected patients were not reliable predictors of outcome (*Table 2*).

The length of the residual portion of the first rib did not affect the results. The mean stump length was 27 mm (range 0–62 mm) in the group with long term success and 29 mm (range 0–81 mm) in the group with residual symptoms. The long stumps were associated with the early intraperiosteal resections.

Discussion

A classification of surgical results into categories such as fair, improved or good may easily be biased, especially if done by the operating surgeons. Therefore, we tried to use as clearcut a definition as possible for classification when using retrospective data. With this method the operative success rate was only 52 per cent, far lower than in other series. If, however, not only asymptomatic patients but also those showing improvement, as defined both by the patient and by the examining surgeon, were accepted as being good results, an immediate 'success' rate of 77 per cent was achieved. This latter result is nearer those found in other short term series where success rates are typically 80–99 per cent[2–15]. It is likely that, in the present study, there was a significant number of patients with initial symptoms due to causes that were unlikely to be relieved by removing the first rib[16].

It is hard to assess success when there are no satisfactory objective tests for comparing preoperative and postoperative states[17]. Carroll and Hurst[18] noted that some patients who were reported by their surgeons as having improved were subsequently described by others as not having been helped by surgery for TOS. In order to avoid such bias, independent observers were invited to do our long term follow-up examinations. Little more than one-third of patients had a true, permanent success.

Unfortunately, no single predictive characteristic for success was found in the clinical history. Furthermore, none of the preoperative tests used in this study seemed to be of any clinical value. This has already been observed by others[19]. Vascular laboratory studies, functional angiography and classical TOS provocation tests, i.e. Adson's, Eden's and Wright's tests, are all aimed at disclosing vascular compression, which is present only in 1–2 per cent of all patients with TOS[17]. A lack of uniform neurophysiological findings means also that there is no reliable neurophysiological method in patients with TOS[20–22].

The high frequency of prolonged dysaesthesia in the area innervated by the intercostobrachial nerve accords with the observation of an area of permanent numbness in 20–27 per cent of limbs in other series[2,23]. Although intraperiosteal resection of the first rib might be linked to regrowth of the rib, the length of the stump was not related to the long term outcome in the present series.

The results of this study suggest that resection of the first rib is the treatment of choice for only a limited number of carefully selected patients. The selection, however, is very difficult since no objective tests of proven value exist.

Unusual cause of thoracic outlet syndrome

R. M. R. McAllister, G. Watkin and M. Adiseshiah

Bloomsbury Vascular Unit, The Middlesex Hospital, London, UK

Correspondence to: Dr R. M. R. McAllister, Department of Surgery, The Middlesex Hospital, Mortimer Street, London W1N 8AA, UK

Case report

A 22-year-old builder presented with a 4-year history of recurrent pain in the right wrist, a 3-month history of paraesthesia radiating from the right wrist to the elbow, and intermittent right-sided neck pain, all of which were exacerbated by sneezing. The symptoms began when he started a new job which involved heavy lifting.

On examination he was generally fit. The upper limb pulses were present but with a reduced volume in the right radial. The systolic blood pressure was lower by 20 mmHg when measured in the right arm. A loud bruit was audible over the right subclavian artery. There was no muscle wasting in the arm but there was reduced power in the intrinsic muscles of the hand, together with reduced perception of pin-prick and light touch in the seventh and eighth cervical nerve root sensory distribution. Radiographs excluded a cervical rib. Electromyography identified a conduction abnormality in the ulnar nerve, not localized to the elbow. An intravenous digital subtraction angiogram showed a kink in the right subclavian artery at the first rib (*Figure 1*).

Right first rib resection was carried out via a standard axillary approach[1]. An abnormal swelling at the origin of the subclavian artery gave the impression of a haematoma around the artery. Median sternotomy was performed and the innominate artery was controlled. The first thoracic nerve root was defined within the thorax and the lesion previously thought to be a haematoma was found to arise within the nerve root. The mass was excised, a drain was inserted and the chest was closed. Histopathology of the specimen revealed a benign schwannoma with degenerative features (*Figure 2*). The patient recovered and was discharged home.

Discussion

Pang and Wessel found no reports of brachial plexus tumours causing thoracic outlet obstruction in a review of 159 papers between 1846 and 1987[2]. Lusk *et al.* reported 147 patients with primary tumours of the brachial plexus in the world literature since 1886[3]. In a series of 600 brachial plexus lesions between 1969 and 1985, 384 were operated upon and 57 were tumours[3]. Eight of these were benign schwannomas. Presentation was usually as a painless, palpable, mass with mild or no neuronal loss, which contrasts with the present case in which the tumour was out of reach and caused the pressure symptoms of thoracic outlet obstruction. Five of the eight schwannomas were located on the fifth or sixth nerve root, or on the upper trunk. The remainder were on the lower trunk or on the lateral and the medial cords. In another review of 480 benign schwannomas, Gyhra *et al.* found only 24 arising from the brachial plexus[4]. A case report was given of such a patient with intrathoracic extension of the tumour which had not been previously reported. The difficulties of diagnosing brachial plexus tumours before operation have been emphasized, especially when these tumours are inaccessible to palpation[5,6].

Thoracic outlet syndrome caused by a schwannoma of the brachial plexus is exceptionally rare. We have found no reports of such a presentation in the literature.

Combined internal and external biliary fistulae treated by percutaneous cholecystlithotomy

M. G. Davies, E. Tadros, S. Gaine, G. P. McEntee, T. F. Gorey and T. P. J. Hennessy

Department of Clinical Surgery, Trinity College and Department of Surgery, St. James's Hospital, Dublin, Ireland

Correspondence to: Mr M. G. Davies, Department of Surgery, St. James's Hospital, James' Street, Dublin 8, Ireland

Spontaneous biliary fistulae are rare, occurring in approximately 3 per cent of all patients undergoing biliary surgery, and they usually communicate with the duodenum[1,2].

Case report

An 84-year-old man was referred with a 3-month history of a discharging sinus in the right hypochrondrium. The patient had been admitted 1 year previously with an episode of acute cholecystitis; gallstones were confirmed on ultrasound scan and he settled on conservative treatment. The patient also had obstructive airways disease, congestive cardiac failure and chronic renal failure. A sinogram revealed cholecystcutaneous fistulae, multiple large gallstones and cholecystduodenal fistulae; the remainder of the biliary system appeared normal (*Figure 1*). The tract was too small and tortuous to allow cannulization.

In view of the patient's poor medical condition, direct exploration of the external cholecystcutaneous fistulae was undertaken under local anaesthesia. A small 3-cm incision was made after the tract was dilated, and six large gallstones were removed using a Desjardin's forceps. A 12 Fr Fogarty catheter was inserted, the catheter was brought out through a separate skin incision, and a corrugated drain was placed in the fistula tract. Postoperative recovery was uneventful, and a catheter cholangiogram at 9 days showed a patent biliary system with contrast draining freely into the duodenum. At review, 3 months later, the patient was well, the fistula tract had closed and an oral cholecystogram was normal.

Discussion

In 1670, Thilesus described the first external biliary fistula and, in the 19th century, when the condition was common, Courvoisier reported 169 cases of spontaneous external fistula formation[3,4]. However, only 45 further cases have been reported to date with only nine cases reported from 1944 to 1985[5]. The dramatic fall in incidence is attributable to the advent of modern biliary tract surgery.

Spontaneous biliary fistulae are usually the result of acute suppurative cholecystitis, and they drain into the duodenum in 75 per cent of all cases. Fistula formation into the colon, bronchial tree, stomach and urinary tract have also been reported but these fistulae are extremely rare[6–8]; only one case of combined internal and external biliary fistulae has been reported to date[5]. In that case, the patient who was otherwise healthy was treated successfully by cholecystectomy and excision of the fistulous tracts. However, in high risk patients, percutaneous removal of the stones should be considered, and with an existing tract to the gallbladder endoscopic access may be feasible if the tract can be dilated. The presence of a patent cystic duct and distal biliary tree following the procedure should ensure that the cholecystcutaneous fistula closes spontaneously when the drain is removed.

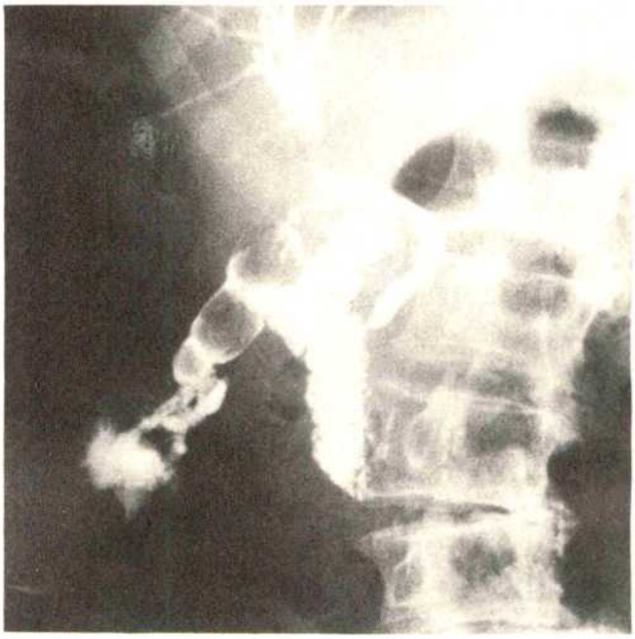

Figure 1 *Contrast fistulogram showing multiple gallstones in the gallbladder and fistulae to the skin and duodenum*

Attachment of indium-111 labelled endothelial cells to pretreated polytetrafluoroethylene vascular grafts

J. S. Budd, P. R. F. Bell and R. F. L. James

Department of Surgery, University of Leicester, Leicester Royal Infirmary, PO Box 65, Leicester LE2 7LX, UK

Correspondence to:
Mr J. S. Budd

This study investigated the effect of different surface coatings on endothelial cell attachment to polytetrafluoroethylene (PTFE) vascular grafts. Small segments of PTFE vascular grafts were precoated with one of a number of substances: gelatin, poly-l-lysin, fibronectin, or collagen type I, III or IV. Indium-111 labelled endothelial cells were then seeded on to the grafts and left for either 10, 30, 60 or 120 min. The unattached cells were removed and the degree of cell attachment was calculated. All coatings were significantly better at enhancing endothelial cell attachment at all times compared with controls, and fibronectin was significantly better as a coating material than any other material used. By pretreating with a substance such as fibronectin, the number of endothelial cells attaching to PTFE vascular grafts can be greatly increased, thereby enhancing the cell seeding process.

Keywords: Vascular grafts, endothelial cells, cell seeding

Autogenous saphenous vein remains the best small-calibre arterial substitute at the present time. However, it is often unavailable or unsuitable and in this situation prosthetic grafts offer the only alternative. Although satisfactory results have been obtained using prosthetic grafts in larger vessels such as the aorta, results using prosthetic grafts in the infrainguinal region, especially below the knee, have been disappointing. The absence of a functional endothelial cell monolayer on the luminal surfaces of these small-diameter prostheses is one of the reasons that they have failed to live up to their expectations[1]. Recent studies in animal models have shown that seeding endothelial cells on to the luminal surface of prosthetic grafts before implantation accelerates graft endothelialization, reduces luminal thrombus formation and improves short-term patency[2,3]. In humans, however, the number of endothelial cells that can be harvested from the limited lengths of donor vessel available is considerably lower than in animal models[4] and this has hampered progress with human endothelial cell seeding. Various substances such as gelatin and fibronectin are known to enhance cell attachment and subsequent spreading on tissue culture plastic[5]. The aim of the present study was to optimize the use of the limited number of endothelial cells available by improving their attachment on to the graft material using various surface coatings. Human umbilical vein endothelial cells were used for this purpose.

Materials and methods

Endothelial cell cultures

Endothelial cells were harvested from human umbilical veins. Umbilical cords were collected within 24 h of delivery and all clamp marks and needle holes were removed. The umbilical vein was cannulated at either end and was then flushed with 10 ml minimum essential medium (MEM) to remove any residual blood. Three-way taps were connected to the cannulae. The vein was then distended with 5 ml 0·1 per cent collagenase solution (CLS I, Worthington Biochemical, Freehold, New Jersey, USA; $CaCl_2$ 15 mmol/l) prewarmed to 37°C, and the whole cord was incubated for 15 min at 37°C. After incubation the vein was flushed through with 20 ml MEM to remove dislodged endothelial cells and the resulting cell suspension was centrifuged for 7 min at 200*g* and 4°C. The cell pellet was resuspended in 5 ml complete medium. This consisted of medium M199 containing 20 per cent fetal calf serum, 100 units/ml penicillin, 100 μg/ml streptomycin, 20 mmol/l Hepes buffer, 2 mmol/l glutamine, 1 mmol/l pyruvate (all from Flow Laboratories, Irvine, UK), 20 μg/ml endothelial cell growth supplement and 90 μg/ml heparin (both from Sigma Chemical Company, Poole, UK), and the cells were finally plated on to a 25 cm^2 tissue culture flask. The cells were incubated at 37°C in 95 per cent O_2/5 per cent CO_2 for 3–7 days until they reached confluence.

Identification of cells

Confirmation of endothelial cell identity was made by appearance at confluence using phase contrast microscopy and by confirming the presence of von Willebrand factor using a rabbit antihuman von Willebrand factor (Dakopatts, Glostrup, Denmark).

Labelling of endothelial cells

Once at confluence, the cells were harvested with 0·1 per cent trypsin in 0·02 per cent ethylene diamine tetra-acetic acid at 37°C. The trypsin was then inhibited by adding excess MEM containing 20 per cent fetal calf serum. The resulting cell suspension was centrifuged for 7 min at 200*g* and 4°C, and the cell pellet was resuspended in a small volume of serum-free medium. A mean (s.e.m.) of 1·68 (0·12) $\times 10^6$ cells was then labelled with 100 μCi ^{111}indium oxine at room temperature for 15 min. After labelling, the cells were washed three times with MEM and finally resuspended in 5 ml MEM with 10 per cent fetal calf serum in readiness for seeding. At this point a small sample of the labelled cell suspension was taken for cell counting and viability studies using trypan blue. Labelling efficiency was also determined at this time.

Preparation of graft surfaces

Expanded polytetrafluoroethylene (PTFE) vascular grafts of standard thickness (0·64 mm) and with an internal diameter of 6 mm were used. The grafts were cut into short segments and opened lengthways to expose the luminal surface. Each segment was then immobilized in a well constructed from a modified Eppendorf tube (*Figure 1*). The well allowed 0·5 cm^2 of the luminal surface of the PTFE to be exposed. All subsequent surface treatments and endothelial cell seedings were performed on this immobilized surface. Gelatin (1 per cent), poly-l-lysin (20 μg/ml), fibronectin (20 μg/ml), and collagen types I, III and IV (20 μg/ml) (all from Sigma, UK and made up in MEM) were compared as substrates for cell attachment on PTFE. One hundred microlitres of the solution to be tested were placed in a well and incubated at 37°C for 2 h. The solution was then removed and the surface was air dried before seeding. Controls were coated with MEM.

Attachment of endothelial cells to graft material

One hundred microlitres of the labelled cell suspension were added to individual wells containing graft segments with different coatings. After incubation in 95 per cent O_2/5 per cent CO_2 at 37°C for periods ranging from 10 to 120 min, the unattached cells were removed and saved (ten

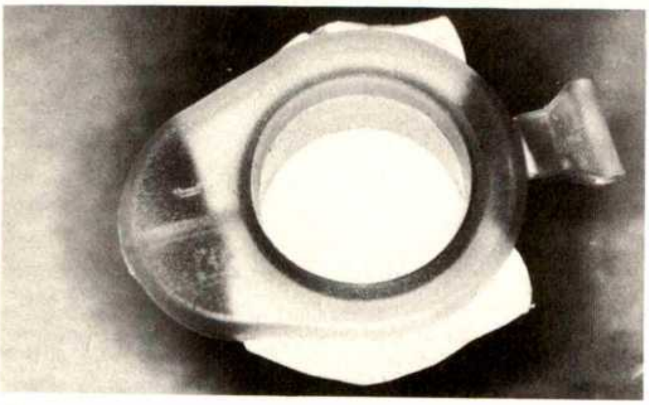

Figure 1 *Endothelial cell seeding chamber as seen from above*

separate studies were carried out on each coating for each incubation time). The graft surface was then washed gently and the washings were added to the previously removed cells. Radioactivity on the graft segments and in the unattached cells was measured. The degree of cell attachment was expressed as a percentage of the initial cell inoculum by using radiation counts in the following formula:

$$\text{Cell attachment (\%)} = \frac{\text{Counts on graft}}{\text{Counts in washings} + \text{counts on graft}} \times 100$$

Statistical analysis

All data were analysed using both a paired *t* test and Wilcoxon signed ranks test.

Results

Figure 2 shows the typical morphological appearance of endothelial cells on phase contrast microscopy, and the fluorescent localization of von Willebrand factor in the cells (*Figure 3*) confirms their identity. The mean (s.e.m.) number of endothelial cells seeded on to the graft segments was 6·7 (0·5) × 10^4 cells per cm^2. The mean (s.e.m.) labelling efficiency with indium-111 was 19(3) per cent, a figure which corresponds to that obtained by Sharefkin *et al.*[6]. The cell viability after labelling, as determined by staining with trypan blue, was always greater than 96 per cent. Although a similar number of endothelial cells was seeded on to the graft segments each time, we have expressed cell attachment as a percentage of the initial cell inoculum rather than as a finite number. More then ten times as many endothelial cells initially attached to graft coated with fibronectin compared with untreated controls ($P < 0·01$) (*Table 1*). Indeed, all coatings were significantly better at enhancing endothelial cell attachment at all times compared with controls ($P < 0·01$ for all coatings at all times except gelatin and poly-l-lysin at 10 min, where $P < 0·05$). Fibronectin was significantly better as a coating material than any other material used ($P < 0·01$ *versus* all other coatings at all times except collagen type I at 120 min, where $P < 0·05$). The time trend for endothelial attachment to PTFE using some of the coating materials is shown in *Figure 4*. Endothelial cell attachment to fibronectin-coated PTFE reached 50 per cent after 20 min and attained an apparent maximum of 60 per cent at 60 min. In contrast, on uncoated PTFE grafts, just over 5 per cent of cells attached after 20 min, doubling to 10 per cent at 1 h.

Discussion

The endothelial cell monolayer of blood vessels is non-thrombogenic, largely owing to its ability to produce prostacyclin. Unlike most other animals, humans do not endothelialize prosthetic grafts except for short distances at anastomoses[1]. Most of the graft luminal surface therefore remains relatively thrombogenic, especially just after implantation. In the canine model, autologous endothelial cell seeding of prosthetic grafts has led to a confluent endothelial cell monolayer within 4–6 weeks[7,8], with concomitant improvement in graft patency rates, even in situations of relatively low blood flow. In humans, however, there are two main obstacles to practical cell seeding. Firstly, there is a relatively low number of endothelial cells available for immediate seeding and, secondly, there is a low rate of cell retention due to poor attachment to the graft surface[9]. Because only small lengths of donor vessel are available in humans, the potential for increasing the number of cells available for immediate seeding is limited, although Jarrell *et al.* have successfully used omentum to increase the yield of endothelial cells[10]. In order to make full use of harvested cells, the surface of an ideal graft should produce efficient initial attachment.

The present preliminary study has shown that precoating PTFE grafts with fibronectin significantly improved initial

endothelial cell attachment compared with controls. Collagen of all types, but type I in particular, also markedly enhanced the initial cell attachment, but to a significantly lesser degree than fibronectin. This contrasts with the results of Anderson *et al.*[11] who found that collagen was superior to fibronectin, although a truly direct comparison is not possible because they measured the absolute number of cells retained rather than the percentage, as in our study Hasson *et al.*[12] found that gelatin was as effective as fibronectin but these authors coated tissue culture plastic rather than PTFE. Although gelatin did increase attachment on to PTFE in our study, it was not nearly as effective as fibronectin. Other studies have shown that fibronectin coating is superior to PTFE alone, but comparison with other coating materials is lacking[13,14].

Fibronectin seems to be a ubiquitous glycoprotein. It is synthesized by a variety of cells, including endothelial cells, and is present in plasma. It has been shown to promote cell adhesion and spreading and has also been implicated in the regulation of platelet adhesion and aggregation. Since pretreatment of PTFE with fibronectin increases initial endothelial cell attachment, it is reasonable to suppose that it will also facilitate growth to confluence, as it does in *in vitro* tissue culture. However, this process takes time, and in the canine model up to 6 weeks are required for immediately harvested endothelial cells to achieve confluence on PTFE grafts. During this period, parts of the graft surface not covered with endothelial cells remain exposed to blood components and are potential areas for platelet accumulation. One might expect, since fibronectin increases endothelial cell attachment to grafts, that it may also increase platelet attachment on exposed graft surface. Although this has been demonstrated by Seeger *et al.*[15], short-term graft patency was not adversely affected, presumably because of the relative increase in endothelial cell coating promoted by fibronectin. Nevertheless, the exposure of fibronectin-sensitized, non-endothelial cell-coated areas of graft is a potential disadvantage which may preclude the use of this substance when a small number of cells are seeded for a short incubation time. The problem of an initially increased thrombogenicity, before the later development of confluence, could perhaps be countered by the use of antiplatelet agents or by anticoagulation[16].

Further studies of surface preparations are necessary to find the best seeding environment. To eliminate the potential adverse effects of exposed areas of graft or coating material, which may occur when implantation rapidly follows seeding, a delay would seem appropriate to try to produce a confluent endothelial cell monolayer on the graft before implantation The advantages of fibronectin as a coating material might then be utilized more fully and the disadvantage of increased platelet adherence might be avoided.

In premenopausal women with breast cancer, the use of the luteinizing hormone releasing hormone agonist, goserelin, results in the production of serum levels of oestradiol equivalent to those after surgical oöphorectomy or in postmenopausal women. The standard first line hormonal treatment for systemic breast cancer in postmenopausal women is tamoxifen. The combination of goserelin and tamoxifen in premenopausal women has been proposed. We have treated 34 premenopausal breast cancer patients with goserelin (3·6 mg) monthly and tamoxifen (20 mg) twice daily: endocrine data are available on all 34 patients. As with goserelin alone, patients on goserelin and tamoxifen showed transient stimulation of serum follicle stimulating hormone over the first 7–10 days with subsequent low gonadotrophin levels. Serum oestradiol and progesterone levels were reduced to castrate levels in all patients studied; no peaks of serum oestradiol were detected. There is no endocrinological contraindication to the use of goserelin and tamoxifen together in premenopausal women with breast cancer either as adjuvant therapy or in treating advanced disease.

Keywords: Breast cancer, premenopausal, LHRH agonist, antioestrogen, combination

The endocrine and clinical effects of the luteinizing hormone releasing hormone (LHRH) agonist goserelin as the sole initial therapy for premenopausal advanced breast cancer have been reported[1–3]. Goserelin alone produced castrate levels of oestradiol and response rates of 31 per cent, which are equivalent to those seen after surgical oöphorectomy[3].

The antioestrogen, tamoxifen, is widely used as the initial therapy in postmenopausal patients with advanced breast cancer owing to its low toxicity and proven efficacy. The combination of goserelin and tamoxifen together in the treatment of advanced premenopausal breast cancer has a definite rationale, in that having made a patient effectively postmenopausal with goserelin it would then seem reasonable to treat them as postmenopausal patients with tamoxifen. Combining goserelin and tamoxifen therapies would be an attempt to maximize the response to endocrine therapy by increasing the rate and/or the duration of response.

The use of tamoxifen alone in premenopausal patients can cause intermittent peaks of serum oestradiol[4–6] which might over-ride the effect of goserelin therapy alone. Detailed endocrinological assessment of the combination of goserelin and tamoxifen is necessary before it can be recommended for wider use. Here we report the results of 34 patients with premenopausal breast cancer treated with goserelin and tamoxifen together.

Patients and methods

Thirty-four premenopausal patients with a histological diagnosis of breast cancer have been treated with goserelin (Zoladex®, ICI Pharmaceuticals (UK), Macclesfield, UK) and tamoxifen (Nolvadex®, ICI Pharmaceuticals (UK)) in combination as an initial hormone therapy. all patients gave a written informed consent The mean age of the patients on commencing therapy was 43·8 years. median 44 years, range 28–53 years. The sites of disease are shown in *Table 1*. Of the 20 patients with metastatic disease the major sites of disease were bone (six patients), lung (eight patients), bone and lung (four patients) and viscera (two patients)

Before commencing the combination therapy all patients had a full clinical examination and skeletal survey; routine haematological and biochemical tests were carried out, and photographs of any visible diseases were taken. These investigations were repeated at 3-monthly intervals or earlier if clinically indicated. Other investigations (e g. isotope bone scan, computed axial tomographic scan) were carried out if clinically indicated

All patients received goserelin 3·6 mg by subcutaneous injection every 4 weeks, along with tamoxifen 20 mg twice a day Peripheral blood (10 ml) was obtained at the following times: days 0, 2, 8, 15, 22, 29, and weeks 8, 12, 18 and 24. The blood was placed in bottles without anticoagulant; it was centrifuged and the serum was pipetted off and frozen initially to −20°C and later to −70°C.

Sera from all 34 patients treated with goserelin and tamoxifen have been assayed for follicle stimulating hormone (FSH), luteinizing hormone and progesterone using methods previously described[2]. The endocrinology of the combined goserelin and tamoxifen therapy was compared with the previously reported endocrine data from 24 patients who received the monthly goserelin injection alone[3].

A new oestradiol assay has recently been established at the Tenovus Institute. In all the patients who received goserelin alone[3], oestradiol was measured by the old assay. Of the 34 patients who received goserelin and tamoxifen 15 had serum oestradiol measured by the old assay and the remaining 19 by the new assay. Comparison of serum oestradiol in patients on goserelin and tamoxifen *versus* those on goserelin alone is between the 15 patients on the combined therapy who had serum oestradiol measured by the old assay and the 24 patients on goserelin alone all of whom had serum oestradiol measured by the old assay.

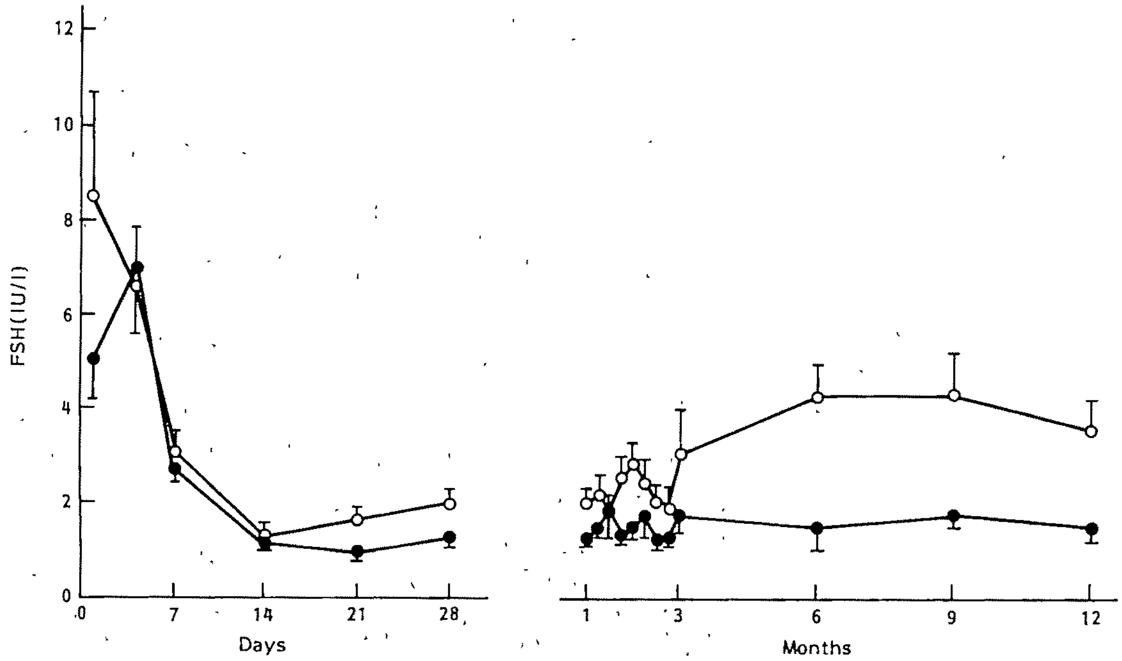

Figure 1 *Mean (s.e.m.) serum follicle stimulating hormone (FSH) levels in 34 patients treated with goserelin and tamoxifen compared with 24 patients treated with goserelin alone.* ○, *goserelin alone,* ●, *goserelin and tamoxifen*

Data on serum oestradiol from the 19 patients on goserelin and tamoxifen who had serum oestradiol measured by the new assay were not entered into the comparison between the two therapies. Data from these 19 patients were reported separately to confirm that castrate levels of oestradiol were obtained and that there were no intermittent peaks of oestradiol on therapy in these patients No correlative data between the differing oestradiol assays are therefore given in this paper except to note that the new assay gives slightly lower serum oestradiol values than the old assay Serum oestradiol concentrations were originally measured using a commercially available kit from Steronti Research Ltd. Subsequent concentrations were determined using a double antibody kit provided by Diagnostic Products Corporation, Whitney, Oxon, UK.

Patients were assessed for response to goserelin and tamoxifen by the UICC (International Union Against Cancer) criteria[7] while adhering to the British Breast Group recommendations[8] that the minimum duration of remission should be 6 months and that an external assessment of response should be carried out; 23 patients were assessable for response, while 11 patients were not assessable for the following reasons. three patients received the combination treatment as adjuvant therapy and eight patients had systemic disease which was unassessable for response by UICC criteria.

Results

Serum FSH, and oestradiol (mean and s.e.m.) levels in patients on the goserelin and tamoxifen combination are shown in *Figures 1* and *2* respectively; a comparison is made with the 24 patients who received the monthly 3·6 mg goserelin injection alone. Serum FSH levels were significantly lower in patients on goserelin and tamoxifen than in patients on goserelin alone ($P < 0.05$; Mann–Whitney U test) at all time points shown in *Figure 1* from 1 month onwards Furthermore the slight upward drift of the serum FSH level in patients on goserelin alone (*Figure 1*) does not occur with the combined therapy, and it would appear that the combination achieves better suppression of serum FSH.

Figure 2 shows that the serum oestradiol levels were decreased to the castrate range by both treatments within 3–4 weeks of the initiation of therapy. There was no difference in the serum oestradiol levels between the two treatment groups at any time from 1 month onwards.

Figure 3 shows that the mean serum oestradiol level was in the castrate range in the 19 patients on goserelin and tamoxifen who had their serum oestradiol level measured by the new assay.

No intermittent peaks of serum oestradiol were noted in any of the 34 patients receiving the combination therapy. There was a transient stimulation of serum luteinizing hormone over the first 7–10 days (peak mean 14·0 International unit/l) with subsequent low levels (<1 International unit/l) Serum progesterone levels were reduced to the castrate range in all the patients studied.

The response rate to the combined goserelin and tamoxifen therapy in the 23 patients assessable for response by UICC criteria was 22 per cent (five patients) partial response with a further 22 per cent (five patients) having static disease. Thirteen patients (56 per cent) had progressive disease within 6 months of commencing the goserelin and tamoxifen treatment

Discussion

Goserelin and tamoxifen is a rational drug combination for treating premenopausal patients with advanced breast cancer but it was necessary to confirm that the two drugs were not clinically and endocrinologically antagonistic. Theoretical objections to the combination lay in the fact that tamoxifen alone can produce intermittent peaks of oestradiol in the serum of premenopausal women[4–6]; the effect of tamoxifen therefore might over-ride that of goserelin.

In the premenopausal woman the use of goserelin alone results in the production of serum oestradiol levels equivalent to those after surgical oöphorectomy or in postmenopausal women, although in a few patients recurrent suppressed peaks of oestradiol were noted[3]. In a small clinical study it has been reported that although the LHRH agonist buserelin (3 × 400 μg intranasally daily) in combination with tamoxifen resulted in a response in three of five premenopausal patients with advanced breast cancer, in four of these five patients serum oestradiol peaks occurred[9]. Serum oestradiol peaks were also reported to have occurred in six of ten premenopausal patients with advanced breast cancer during long term therapy with buserelin alone (3 × 400 μg daily), suggesting that oestradiol peaks were due to insufficient LHRH agonist rather than the tamoxifen therapy In a subsequent study this was confirmed castrate levels of oestradiol were reported when the dose of buserelin was increased[10].

In addition to the endocrinological effects of LHRH agonists via pituitary desensitization it has been suggested that these agents may act directly on breast cancers. Miller and colleagues

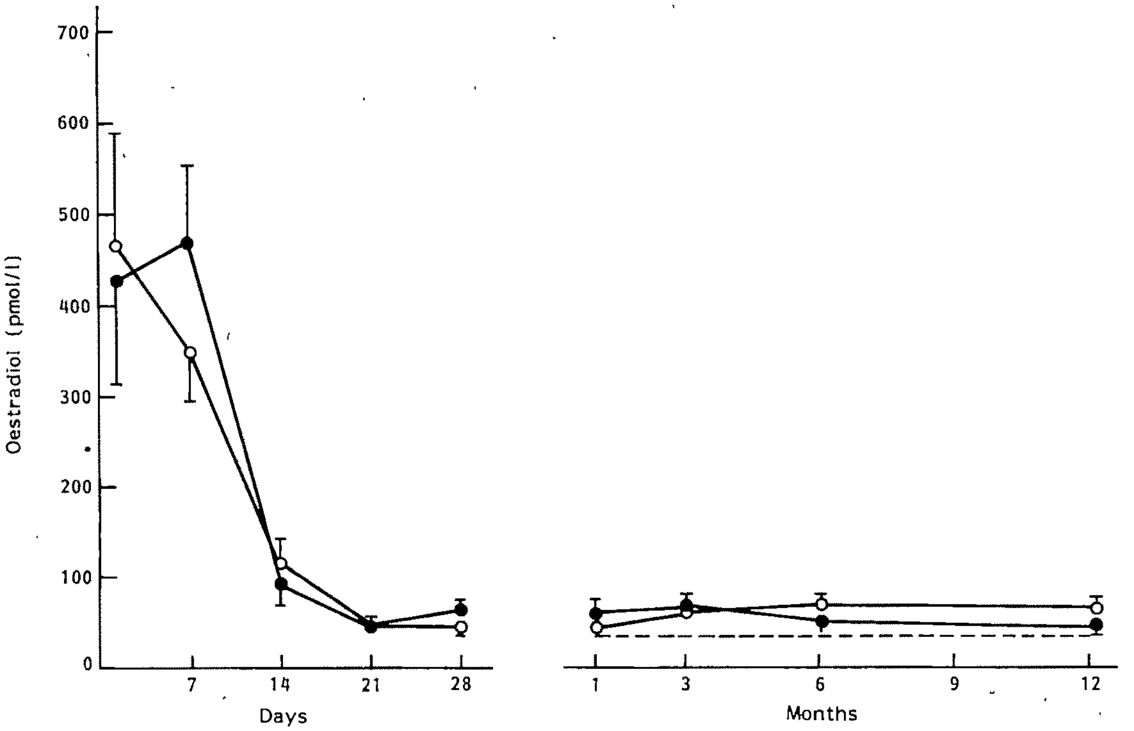

Figure 2 *Mean (s.e.m.) serum oestradiol levels using the old assay in 15 patients treated with goserelin and tamoxifen compared with 24 patients treated with goserelin alone:* ○, *goserelin alone,* ●, *goserelin and tamoxifen,* ---, *castrate level*

reported a direct inhibitory effect of the LHRH agonist, buserelin, on the growth of the MCF-7 breast cancer cells in culture[11]. A subsequent *in vitro* study reported the effects of buserelin and tamoxifen on the growth of MCF-7 human breast cancer cells[12]. Combined administration of buserelin and tamoxifen was less effective than either buserelin or tamoxifen as single agents in inhibiting the growth stimulation of MCF-7 cells by oestradiol. In view of these findings it was important to establish both that goserelin and tamoxifen were endocrinologically not antagonistic and that a clinical response to the combination was seen in premenopausal patients with advanced breast cancer.

Our results show that goserelin and tamoxifen produce castrate levels of oestradiol and progesterone; no peaks of oestradiol have been recorded in the serum of any of the patients reported in this study. On the contrary, serum FSH concentrations are better suppressed in patients on combination therapy than in those on goserelin alone.

On the combination therapy, five of 23 patients (22 per cent) showed a partial response and a further five (22 per cent) had static disease, both for a minimum duration of 6 months. The reported response rate to goserelin alone was 31 per cent with a further 7 per cent showing static disease for at least 6 months[3]. However comparison of the efficacy of goserelin and tamoxifen *versus* goserelin alone was not the intention of this study. The aims were to establish that, in premenopausal patients with advanced breast cancer, the combination of goserelin and tamoxifen was not endocrinologically antagonistic and could produce clinical response rates similar to surgical oöphorectomy; both of these aims have been confirmed.

Comparison of the clinical efficacy of goserelin and tamoxifen *versus* goserelin alone requires a prospective randomized trial. An international multicentre trial is currently in progress to evaluate whether, in premenopausal women with advanced breast cancer, goserelin and tamoxifen together as an initial therapy will increase the response rate and/or duration of response, compared with goserelin alone as an initial therapy with tamoxifen being added later on tumour progression. This combination may also be suitable for adjuvant therapy but possible long term complications need assessment in that situation.

Correspondence to:
Mr I. S. Fentiman

In a prospective randomized study, patients with pleural effusions secondary to breast carcinoma were randomly allocated to be treated by pleurodesis using either intracavitary talc or bleomycin. For 25 assessable treatments in 22 patients, recurrence of effusion was observed in 5 of 15 (33 per cent) of the bleomycin group compared with none in the talc group. It is concluded that talc is superior to bleomycin in controlling pleural effusions secondary to breast carcinoma, but bleomycin may have a role in patients unfit for general anaesthesia or with extensive disease elsewhere.

Keywords: Breast cancer, pleural effusion, chemotherapy, pleurodesis

Malignant pleural effusions are commonly seen as a result of metastatic carcinoma of the breast. The mean time between diagnosis of breast carcinoma and development of pleural effusion is more than 3 years, and the mean survival after presentation with effusion is 14 months[1]. Thus effective symptomatic control can significantly improve patients' quality of life. More than half of these patients have other metastases for which they are receiving or will receive systemic therapy[2]. Only rarely can pleural effusion be controlled by systemic treatment alone, and local management provides the most effective method of control. Many agents are in use for pleurodesis, some with cytotoxic properties (mustine, doxorubicin, bleomycin) and others which are sclerosants (talc, tetracycline), with a wide range of efficacy reported[3]. In this unit talc pleurodesis has been previously tested against mustine and tetracycline and found to be superior to both[4,5]. Promising results have been reported using bleomycin, but it has not been directly compared with talc, and for this reason a prospective randomized trial has been conducted.

Patients and methods

Twenty-nine patients with breast carcinoma who had developed radiographically confirmed pleural effusion were entered into the trial No previous local treatment had been given apart from simple aspiration for initial symptomatic relief None had any evidence of non-malignant causes for the effusion Patients were stratified by the presence or absence of other metastases requiring systemic treatment to enable balanced randomization All the patients had the effusion drained to dryness under general anaesthetic and then were allocated randomly to have either a talc pleurodesis or a single intercostal drain inserted. The latter was followed by instillation of bleomycin 1 mg/kg in 50 ml normal saline after a chest radiograph had shown re-expansion of the lung and when the patient could be postured to facilitate distribution of the drug. This was usually performed within 48 h Both the bleomycin and talc treated cases had only one intercostal drain

Assessment of response

Patients were deemed assessable for response to pleurodesis provided they survived for >1 month after the procedure, and they had a repeat chest radiograph at this time The immediate postpleurodesis film was used as a baseline from which to assess subsequent radiographs Success was defined as a continued absence of reaccumulation of pleural fluid on all follow-up radiographs; any reaccumulation was regarded as treatment failure

Results

Twenty-nine patients entered into the study. One patient who was allocated to the bleomycin pleurodesis deteriorated rapidly, the procedure was cancelled, and the patient died a few days later. Another patient who was assigned to talc was unable to have insufflation of the agent because of loculations. After apparently successful pleurodesis two patients in the bleomycin group and three in the talc group survived for <1 month and so were excluded from the analysis. Thus there were 22 assessable patients of whom nine were treated with talc, 12 with bleomycin, and one had talc on one side and bleomycin on the other. Two patients had bilateral bleomycin pleurodeses. In total, ten talc and 15 bleomycin assessable procedures were performed.

Median follow-up was 24 months. During the period of the study 23 of the 29 patients died, and 16 of these survived for <6 months. In these 16 patients, extrapleural disease was encountered in 23 sites compared with nine in the seven patients who survived for >6 months (*Table 1*). Seven patients in the talc and six in the bleomycin group were receiving systemic treatment for disseminated disease. The two groups were similar with regard to age at diagnosis of breast carcinoma and menopausal status, but there were more patients with stage 3 disease in the talc group (*Table 2*). The mean time to development of effusion was shorter in the talc group than in the bleomycin group (46 *versus* 55 months). There was also a longer mean delay between diagnosis of effusion and treatment in the talc group (6·6 *versus* 4·8 months).

In the talc group none of the 10 patients developed evidence of relapse of the effusion compared with 5 of 15 (33 per cent) in the bleomycin group (Fisher exact test $P = 0{\cdot}057$) after a mean follow-up of 9 months. Two patients in the bleomycin group underwent subsequent talc pleurodesis with significant symptomatic improvement in one, but no benefit for the other

because of a loculated effusion. The mean survival following pleurodesis in the two groups was identical at 9 months. The procedure was well tolerated and none of the patients developed postoperative complications attributable to it. In fact there was only a minimal degree of postoperative pain, experienced equally by the patients in both groups, and this responded to simple analgesia without need for opiates. The pain was mostly related to the chest drain site. Pleuritic pain was not observed in the talc group, which could be because of the use of non-iodized talc.

Discussion

In this prospective randomized study, talc was shown to be more effective than bleomycin in controlling malignant pleural effusion secondary to breast carcinoma. Although the difference did not quite reach statistical significance, the absence of recurrence in the talc group lends support to the previously reported efficacy of talc in controlling malignant effusions[3,4,6]. To achieve an 80 per cent power of showing the difference at 5 per cent significance level, a further 69 patients would have to be accrued to the trial and this was considered inappropriate. It is likely that, in addition to the inherent effective sclerosant property of talc, its immediate installation after drainage to complete dryness of the pleural cavity contributes to the high rate of success.

Some interesting points emerged from this study. Firstly, 41 per cent of the patients had bilateral and 18·5 per cent contralateral effusions, which suggests mechanisms other than lymphatic obstruction due to direct transthoracic wall lymphatic infiltration[7,8]. Secondly, the median postpleurodesis survival in the group of patients who died was only 2 months (range 0·5 – 16 months) with a median delay of 6 months (range 0·5–48) between diagnosis and treatment. This suggests that for the procedure to be of maximum benefit it should be undertaken as early as possible in the course of the disease. Thirdly, a consideration should be given to the extent of associated tumour burden in order to avoid subjecting patients with very short life expectancy to an unnecessary operation. In this study, there appeared to be evidence of greater tumour load in the patients who survived <6 months compared with those with >6 months survival. The site of extrapleural recurrence did not help us to recognize patients with very short survival. This study differed from previous studies conducted in this unit in that only one intercostal drain was used. It has shown that talc is equally effective as pleural sclerosant with either one or two drains, and the former is preferable both for simplicity and for patient comfort.

Talc remains the most effective agent for controlling malignant pleural effusions in patients who are fit enough for general anaesthesia. The procedure should be undertaken as soon as the effusion is symptomatic and in those patients with minimal disease elsewhere. Patients with pleural effusion and extensive metastases are probably best managed by simple aspiration on the ward as they have a short survival, although present methods of determination of likely length of survival are very imprecise.

Fibromatosis of the breast

J. K. Murphy, A. M. Barlow* and N. G. Graham†

*Department of Pathology, University of Leeds, Leeds LS2 9JT and Departments of *Pathology and †Surgery, Huddersfield Royal Infirmary, Huddersfield HD3 3EA, UK*

Correspondence to: Dr J. K. Murphy

Ninety-five per cent or more of primary breast neoplasia is of epithelial origin; a small percentage is of mesenchymal origin[1]. Fibromatosis is a locally infiltrative proliferation of well differentiated fibroblasts, which show little atypicality and lack the potential for metastasis, in a collagenous stroma[2,3]. Fibromatosis of the breast accounts for less than 0·2 per cent of all primary breast neoplasms[4,5]. Many of the reports of fibromatosis arising in the breast are limited by lack of follow-up information[6]. We present a case of fibromatosis of the left breast in a 70-year-old woman followed for 17 years.

Case report

A 70-year-old nulliparous Caucasian woman with a past history of fibrocystic change in a left breast biopsy (1964) presented in 1971 with a 2-month history of a 5 × 3 cm nodule in her left breast in the vicinity of the old healed surgical incision. She underwent a hysterectomy for leiomyomata at 50 years of age. There was no family history of breast disease and no history of exogenous hormone therapy. Bilateral mammography demonstrated a suspicious lesion with an infiltrative edge in the left breast highly suggestive of malignancy (*Figure 1*).

Histology of the excised nodule showed a poorly demarcated fibrosarcoma (grade not stated) and because of the histology and mammography report a left simple mastectomy was performed. No residual tumour was demonstrated. Subsequently, 3 and 5 cm diameter nodules were excised from the anterior chest wall in the vicinity of the previous surgery at 12 and 18 months respectively. These were of similar appearance to the initial nodule. A 21-day course of fractionated radiotherapy (3750 cGy) was given to the left anterior chest wall because of the aggressive nature of the lesion.

Five further nodules of similar histological appearance were excised at 6- to 18-month intervals to 1978. They ranged from 1 to 3 cm in diameter and occurred lateral to the previous surgical scars and extended into the left axilla. A 10-year free interval followed to September 1988 when the patient presented with a 3 cm diameter hard fixed nodule in the left axilla which was excised.

At no stage during the 17-year period was there evidence of systemic upset, metastases or lymph node involvement by the process.

Reviewing the histology, including all archival material, similar lesions composed of a population of fibroblasts in interweaving bundles and fascicles in a collagenous stroma (*Figure 2a*) were demonstrated. Areas of variable cellularity were seen, particularly in the later material, which included hyalinized acellular parts. Cytologically there was little atypicality with scanty mitotic figures (fewer than 2 per 10 × 20 field) in all lesions. The periphery of the lesions showed finger-like extensions of the tumour infiltrating surrounding fat and muscle (*Figure 2b*). Trapped and necrotic muscle fibres were present in these areas. Focal lymphocytic infiltrates were present particularly at fat or muscle interfaces. Breast tissue was seen in the early specimen only, with ducts in close proximity to the edge of the infiltrative lesion. The lesion was not related to skin or deep muscle. In retrospect this lesion is best regarded as a benign fibromatosis of the breast.

Discussion

Fibromatosis of the breast is a rare lesion with only 21 cases in the literature[7–15] to 1987. In an extensive review by Wargotz *et al.*[6] 28 further cases were reported. Many of the cases lack follow-up studies to observe the natural history of the process. The patient in this report demonstrates the typical history of these lesions with a potential for multiple recurrences if not adequately excised. The possibility of a well differentiated fibrosarcoma may be difficult to exclude at initial evaluation[7,12,16,17].

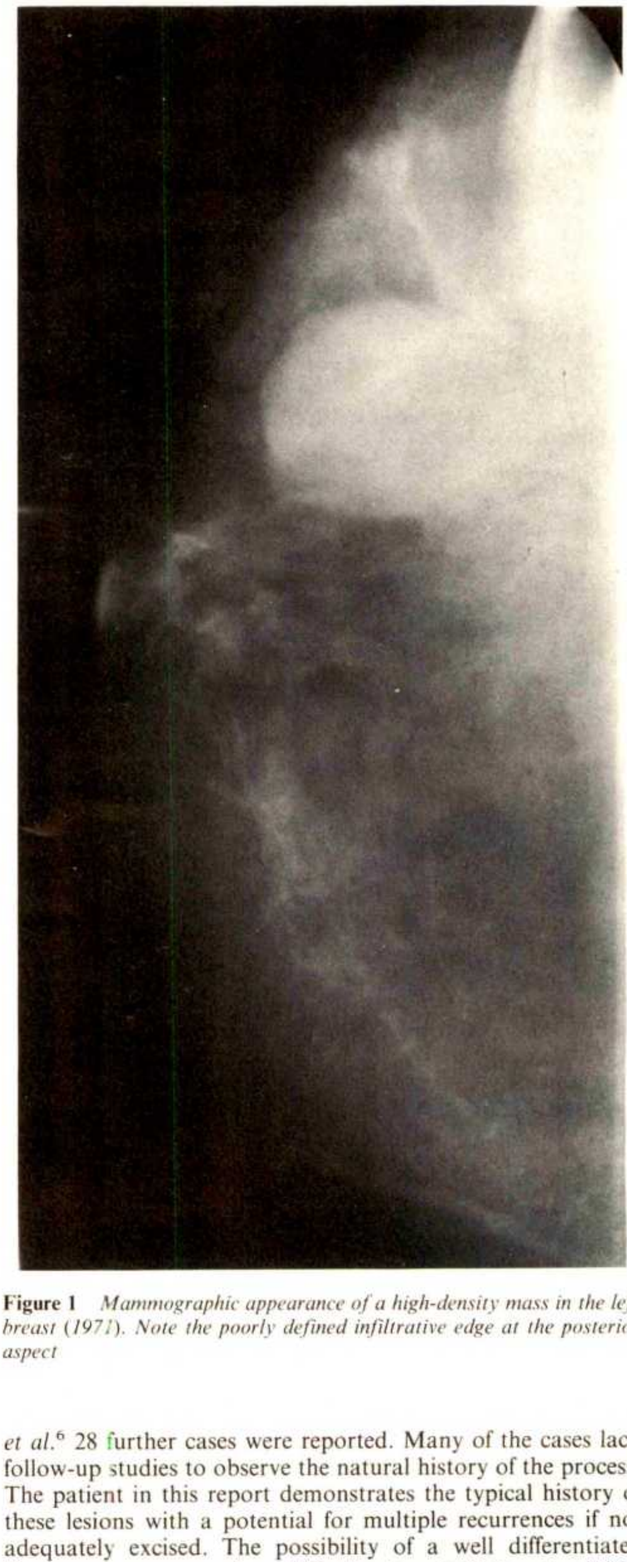

Figure 1 *Mammographic appearance of a high-density mass in the left breast (1971). Note the poorly defined infiltrative edge at the posterior aspect*

Mammograms in eight cases of fibromatosis, including this case, have suggested a malignant lesion[8,10,14,18]. The radiographs show a hyperdense nodule with a poorly defined border and often an infiltrating edge. Fine needle aspiration biopsy for cytology of fibromatosis gives a false positive diagnosis of carcinoma[8]. Lesions of variable cellularity could be subject to sampling error and false-positive diagnoses. Traumatic[19], genetic[14,15] and hormonal[20] factors are proposed as aetiological agents for primary breast fibromatosis. All

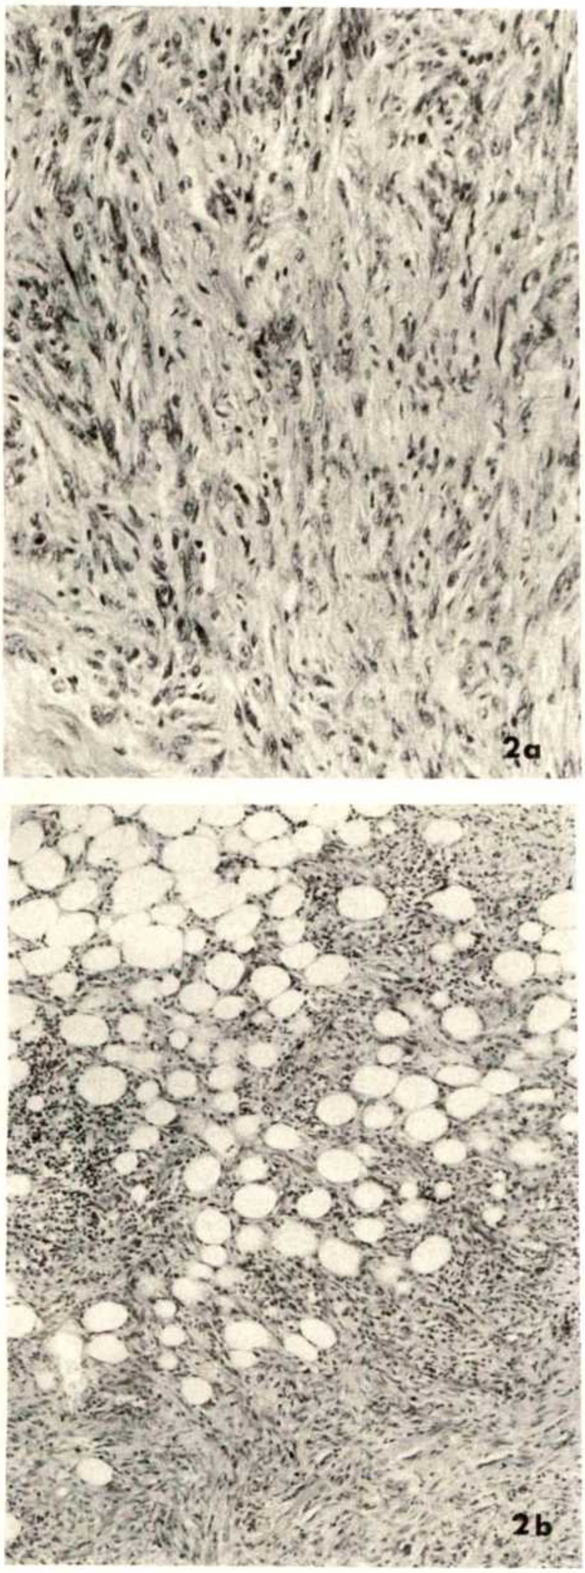

Figure 2 **a** *Representative area of the lesion showing a fascicular arrangement of proliferating fibroblasts* (× *400*). **b** *Edge of the lesion showing infiltration of fat by fibroblasts* (× *400*)

patients have been women[6]. Breast fibromatoses are histologically similar to abdominal fibromatoses or desmoids, which occur at childbearing age and are probably related to stretching of the abdominal musculature by the gravid uterus. The peak incidence of breast fibromatosis is 43 years of age[6] with many occurring in older subjects, suggesting a different pathological process from that of abdominal fibromatosis.

An incisional biopsy in the left breast at the same site, 7 years before presentation of this patient, may have been a contributory factor to the later development of fibromatosis.

Of the series from the Armed Forces Institute of Pathology, 32 per cent had evidence of fibrocystic disease, which was histologically documented in some cases[6]. The 10-year disease-free interval in this case, after repeated recurrences, must reflect on the variable biological behaviour of these processes. The recommended surgical treatment for fibromatosis is wide local excision in view of the often aggressive infiltrative and recurring nature of the process[9,11].

The possibility of fibromatosis of the breast needs to be considered in the population screened in the current national programme[21], especially in those with mammograms and aspirates with false-positive malignant results.

Sample size in fine needle aspiration biopsy

J. Kreula, S. Bondestam and P. Virkkunen

Department of Diagnostic Radiology, Helsinki University Central Hospital, Helsinki, Finland

Correspondence to:
Dr S. Bondestam, Department of Diagnostic Radiology, Meilahti Hospital, Helsinki University Central Hospital, SF-00290 Helsinki, Finland

The weights of biopsy specimens from bovine liver taken for fine needle aspiration cytology (FNAC) by three groups of physicians, were compared. The groups differed from each other in their extent or degree of experience in FNAC. When the physicians used their normal technique, the mean sample weight increased significantly with experience, from 4·6 mg in the least experienced group to 17·2 mg in the group with the longest experience. Thirty-six per cent of the samples taken by the group with the least experience were in the weight class 0–2 mg, whereas no such samples were encountered for the other groups. When all the physicians were advised to use the same, standard technique there were no statistically significant differences in mean sample weight between the groups or in the proportion of samples in class 0–2 mg. Sample weights correlated significantly ($P<0.001$) *with cell counts. This study shows that differences in the technique of FNAC are responsible for differences in sample weights and cell counts, including the number of the acellular samples obtained. This could explain in some part the wide variation in the reported accuracy rates of FNAC.*

Keywords: Fine needle aspiration cytology, cell yield, sample size, technique

The improved awareness of the clinical utility of biopsy for fine needle aspiration biopsy cytology (FNAC) has been responsible for the increase of FNAC performance. This development is partially related to advances in imaging techniques and the refinement of cytological methods. Nuclear magnetic resonance, computed tomography (CT) and sonography have provided improved sensitivity of tumour detection and guided needling to allow tissue sampling from formerly inaccessible sites[1]. In addition to conventional morphological analysis by light microscopy, FNAC samples lend themselves to flow cytometry, tissue culture, biochemical analysis, ultrastructural study, immunological analysis for specific markers, detection and measurement of hormone receptors, and the monitoring of therapy and its effect on malignant tumour cells[2].

However, all these sophisticated methods are inappropriate if cells cannot be aspirated from the target tissue. Studies have shown that up to 43 to 49 per cent of samples for FNAC may be unsatisfactory because of poor yield of representative cells[3,4]. The technique of FNAC has not been studied systematically under controlled conditions. There is no generally accepted technique for FNAC; as a result, each physician tends to use a personal technique. This study shows how this reflects on sample size, explaining some variations in the accuracy of the method[3–10].

Materials and methods

The weights of FNAC biopsy samples taken by three groups of physicians were compared. The groups differed from each other in their experience of FNAC as follows: 'young residents' (five) with a mean of 25 (range 10–40) performed biopsies; 'old residents' (four) with a mean of 75 (range 50–100) biopsies; and 'seniors' (three) with a mean of 750 (range 200–2000) biopsies. Each physician performed 20 FNAC biopsies using his or her usual technique ('free technique'). Thereafter the physicians were required to take ten samples using a 'standardized technique'. In the latter, the tip of the needle was inserted into the target, after which the plunger was pulled back to the 10 ml mark. The physicians were advised to move the needle within the target ten times with a frequency of three strokes per second and with a stroke amplitude of 1·5 cm, suction being maintained throughout. The suction was released before the needle was withdrawn.

Disease-free bovine liver was used as the target tissue. All specimens were taken within 3 h of slaughter. Only the peripheral layer of the liver was used in the experiment to avoid large blood vessels and bile ducts.

A syringe holder (Cameco®, Cameco AG, Täby, Sweden) with a 10 ml disposable syringe was attached to a 22 gauge × 40 mm disposable needle (Terumo Neolus®, Terumo Europe N. V., Leuven, Belgium). A tiny wad of cotton was placed into the hub of each needle to avoid the entry of the specimen into the syringe. The needles with filters were weighed before and after FNAC using a balance (Mettler® Type H 15, E. Mettler, Zurich, Switzerland), accurate to 0·1 mg, standard deviation 0·05 mg). The outer surface of the needle was wiped clean before weighing. The filter did not affect the suction force or its rate of increase, as measured at the needle tip by a pressure sensor (Honeywell Micro Switch® 136 PC 15 G, Honeywell Incorporated, Microswitch Division, Freeport, Illinois, USA) connected to a digital storage oscilloscope (Tektronix® 2210, Tektronix UK Limited, Hoddesdon, UK).

The relationship between weight and cell count of the sample was analysed by microscopical cell counting of specimens with known mass at a magnificiation of × 100. For this, the specimens were fixed in 50 per cent ethanol, collected on a Millipore® (Millipore S. A., Mollsheim, France) filter, and stained with Papanicolaou's stain. For each specimen, the cell count of 30 fields was calculated. The total cell count was obtained by multiplying the mean value per view field by 1.0×10^4, which was the ratio between the area of the Millipore filter and that of the view field.

Lilliefors modification[11] of the Kolmogorov–Smirnov test was used to analyse the normality of the mass distribution curves. Means were compared using Student's t test for unpaired samples, and proportions by using the χ^2 test.

Results

With the free technique, the mass distributions were positively skewed and therefore subjected to square root transformation to obtain better normal probability plots before comparing the mean sample weights obtained by the three groups (*Table 1*). After transformation back to the original scale, the mean (95 per cent confidence interval) weight of the specimens taken by seniors was 17·2 mg (15·1–19·5 mg), by old residents 10·5 mg (9·2–11·8 mg) and by young residents 4·6 mg (3·6–5·8 mg; *Figure 1*). The differences were statistically highly significant (*Table 1*). When the standardized technique was used the corresponding values were: seniors, 10·9 mg (9·1–12·7 mg); old residents, 11·6 mg (10·1–13·0 mg); young residents, 10·2 mg (8·2–12·2 mg; *Figure 1*). There was no statistically significant difference between the groups (*Table 1*).

Table 1 *Comparison between the mean sample weights obtained by three groups of physicians*

	Technique	Difference between means	95% confidence interval for difference between means	Student's *t* value	d.f.	*P*
'Seniors' *versus* 'old residents'	'free'	0·9	0·6 to 1·2	5·6	138	<0·001
'Seniors' *versus* 'young residents'	'free'	2·0	1·6 to 2·4	10·2	158	<0·001
'Old residents' *versus* 'young residents'	'free'	1·1	0·7 to 1·4	6·3	178	<0·001
'Seniors' *versus* 'old residents'	'standard'	−0·7	−2·9 to 1·5	−0·6	68	0·52
'Seniors' *versus* 'young residents'	'standard'	0·7	−1·9 to 3·2	0·4	78	0·66
'Old residents' *versus* 'young residents'	'standard'	1·4	−1·6 to 4·3	1·1	88	0·29

Values obtained by a 'standardized technique' are in original scale; values obtained by a 'free technique' have been subjected to square root transformation

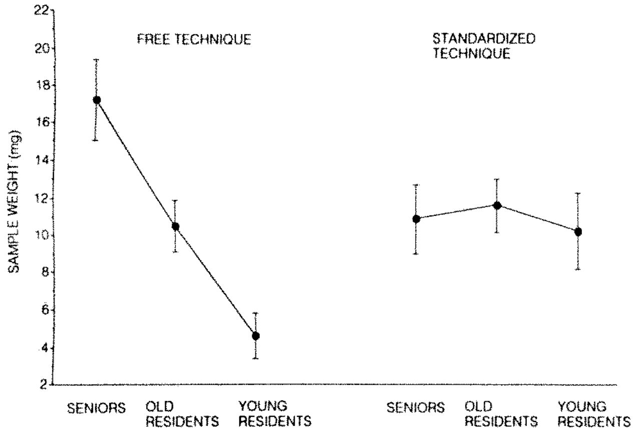

Figure 1 *Mean sample weights with 95 per cent confidence intervals obtained by three groups of physicians using a 'free technique' and a 'standardized technique'*

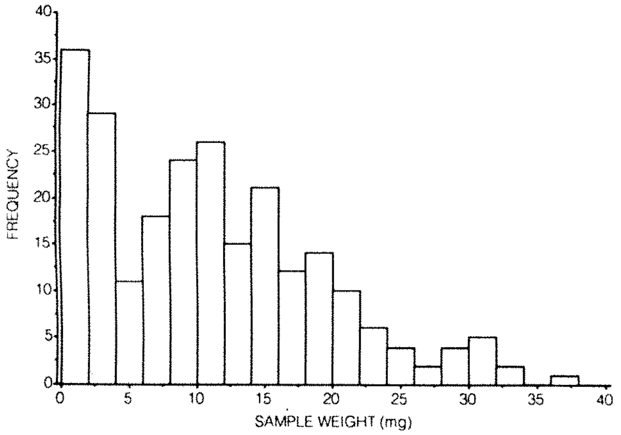

Figure 2 *Frequency distribution histogram of all sample weights obtained by a 'free technique'*

Figure 2 shows the frequency distribution histogram of all samples taken with the free technique. Division of the range of masses into 20 classes of equal size determined 0–2 mg as the lowest weight class. When the free technique was used, 36 per cent of samples (36 of 100) taken by young residents fell into this class, whereas none of the samples taken by old residents (80) or seniors (60) did so. This intergroup difference was statistically significant ($P<0{\cdot}001$). With the standardized technique (not shown) there was no statistically significant difference between the groups, the corresponding proportions being 8·0 per cent (four of 50), 2·5 per cent (one of 40) and 3·3 per cent (one of 30); $\chi^2=1{\cdot}48$, d.f. $=2$, $P=0{\cdot}48$.

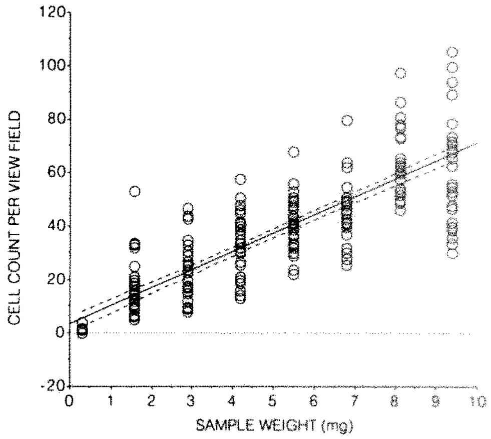

Figure 3 *Correlation of sample weight with cell count per view field at a magnification* ×*100* ($r=0{\cdot}85$, $n=240$, $P<0{\cdot}001$)*. Regression line* $y=6{\cdot}8x+3{\cdot}2$ *with a 95 per cent confidence interval*

Figure 3 shows the statistically significant ($P<0{\cdot}001$) correlation between sample mass and the count of liver cells per view field.

Discussion

In clinical studies the accuracy values of FNAC have varied considerably, e.g. in cancer of the breast from about 50 per cent to over 95 per cent[3–10]. Part of this fluctuation can be explained by differences in patient selection[3,4,6,8,10], or in the selection of samples for the preparation of smears[3,4,8], or in the selection of smears for the calculation of accuracy values[3,4,8]. The equipment used in FNAC can be chosen from a variety of needles with different cutting tips, bevels and calibres[9,12–15], from a variety of syringes[4,8,14] and syringe holders[2,3,10,14,16]. For some physicians the syringe holder is omitted[8,9,12]. There are also differences in aspiration technique. Each physician appears to have evolved a favourite method which he terms FNAC. *Figure 2* shows how free choice in the technique of FNAC reflects on sample size when uniform equipment is used.

With the free technique the experienced physicians obtained significantly larger samples (*Figure 1*) and none of the samples was in the smallest weight class, 0–2 mg, whereas 36 per cent of the samples taken by young residents were under 2 mg in weight. This has important clinical consequences as samples containing few or no cells (acellular) appear in this class. When all physicians participating in the study used the standardized technique there were no differences between the three groups (*Figure 1*), suggesting that the major factor causing the intergroup difference with the free technique was the technical procedure itself (e.g. number, amplitude and frequency of strokes, force of suction). As there is a linear dependence between sample weight and cell count (*Figure 3*) the results obtained can also be applied to cell counts. Thus, the cell count of a sample is determined by the target tissue[12] and by the FNAC technique used. With a set target the only way to enhance cell yield is to optimise the FNAC technique. Although cytopathological quality is subjective it seems that an increase in sample size also leads to better sample quality[13,15].

Regarding FNAC in mammary carcinoma, Dixon *et al.*[5,6] noticed that when there were several aspirators, both junior and senior members of the clinic, the sensitivity of the method was only 59–66 per cent and 19–27 per cent of smears were acellular. When this policy was changed so that all FNACs were performed by only one surgeon using a standard technique the sensitivity increased to 99 per cent and only 1 per cent of samples were acellular. The authors emphasized that a major factor determining the quality of specimens was the experience of the aspirator. The present study, however, shows that the sample quality and the number of unsatisfactory specimens is not only dependent on the experience of the aspirator but also on the technique used. In addition, the high sensitivity noted by Dixon *et al.* can be partly related to better targeting by an experienced operator; tactile sense and augmenting the probability of sampling the lesion by the number and direction of needle passes around the suspect area. Finally, additional aspirations will be made until a macroscopically sufficient sample is obtained.

The various recommendations on how FNAC should be carried out are contradictory and indefinite. Furnival *et al.*[8] reported that the rate of technically unsatisfactory aspirates was 24·8 per cent when the needle was gently moved within the tumour and when suction was maintained as the needle was withdrawn. If the needle was moved more actively and the suction released before withdrawing the needle, the frequency of inadequate samples was decreased to 6 per cent. Duguid *et al.*[14] found that failure to maintain suction when the needle is traversing the lesion leads to poorly cellular samples, and that a better cell yield is obtained when suction is maintained during removal of the needle from the target. These authors also observed that wetting the inside of the needle with saline–heparin solution definitely improves the cellularity of smears. According to Zajicek[16], the syringe and the needle must be absolutely dry when FNAC is performed. Although the number of needle passes within the tumour ranges from 2 to 15 in different reports[4,5,7,14], Hartley *et al.*[12] concluded that there appears to be no advantage in exceeding ten passes or in using needles larger than 21 Fr. Andriole *et al.*[13] noted an improvement in sample size and quality with increasing needle bore and obtained the best results with 18 Fr needles.

One explanation for these different observations might be found in the wide range of variables in the technique of FNAC, including suction (force, duration and rate of increase), needle movement (number, frequency and amplitude of passes, angle between the passes, acceleration of movement), needle (size, content, tip configuration) and target tissue. The simultaneous control and measurement of all these variables is difficult or even impossible with the manual equipment used in FNAC. Still, the development of an optimal technique would appear to require an investigation of the effects of each variable separately. So far, no such studies have been reported.

In conclusion, this study demonstrates that the best way to improve sample quality and to avoid acellular samples is improvement of the technique of FNAC. However, the technique has not been studied systematically under controlled conditions and the actual mechanism of cell sampling that occurs during the aspiration biopsy is not clear. As a result there are no generally accepted guidelines on how FNAC should be performed.

Role of fine needle aspiration cytology and computed tomography in the diagnosis of parotid swellings

E. R. T. C. Owen, A. K. Banerjee, A. J. N. Prichard, E. A. Hudson* and A. E. Kark

*Departments of Surgery and *Histopathology, Northwick Park Hospital and MRC Clinical Research Centre, Harrow, UK*

Operations on the parotid gland present a considerable surgical challenge because the anatomy is delicate and the pathology diverse[1]. Formal parotidectomy has become the preferred treatment for space-occupying lesions[2]; this approach has evolved because pleomorphic adenoma is the commonest lesion. This operation can be technically demanding and the residual disabilities are serious in a significant number of patients. Facial nerve palsy is the single greatest problem, and can be temporary (11–82 per cent) or permanent (0–17 per cent)[3]. Masses of benign origin on the other hand require only enucleation and this has a lower morbidity[4]. Therefore, an accurate preoperative diagnosis would allow less radical surgery in some patients and should reduce complications.

Patients and methods

The case notes of 84 patients presenting with a lump in the parotid region over an 8-year period (1981–88) have been reviewed. Following clinical diagnosis of a lump in or related to the parotid gland two additional diagnostic methods have been used.

Forty-four patients (34 men) were investigated by fine needle aspiration cytology (FNAC) using a standard technique. The age range was 17–81 years. The preoperative cytological diagnosis was compared with the final histopathological one after examination of the surgical specimen. In addition, the last 18 patients had a computed tomographic (CT) scan of the parotid region.

Results

The results and accuracy of fine needle aspiration are shown in *Table 1*. The accuracy was 100 per cent with pleomorphic adenoma and 75 per cent with adenolymphoma with no false positive or false negative diagnoses of malignancy. Follow-up ranged from 4 to 96 months with a mean of 30, and there have been no local recurrences to date. Three patients had tuberculosis of the parotid gland diagnosed by FNAC and were treated medically. In all three, FNAC showed the typical appearances of a granuloma, and culture of the aspirate grew mycobacteria.

All CT scans have shown the presence of a tumour in the superficial part of the parotid (*Figure 1*) with deep extension seen in three (*Figure 2*).

Table 1

	Diagnostic	Inadequate	Accuracy (%)
Pleomorphic adenoma ($n=26$)	26	0	100
Adenolymphoma ($n=8$)	6	2	75
Carcinoma ($n=4$)	4	0	100
Others ($n=6$)	5	1	–

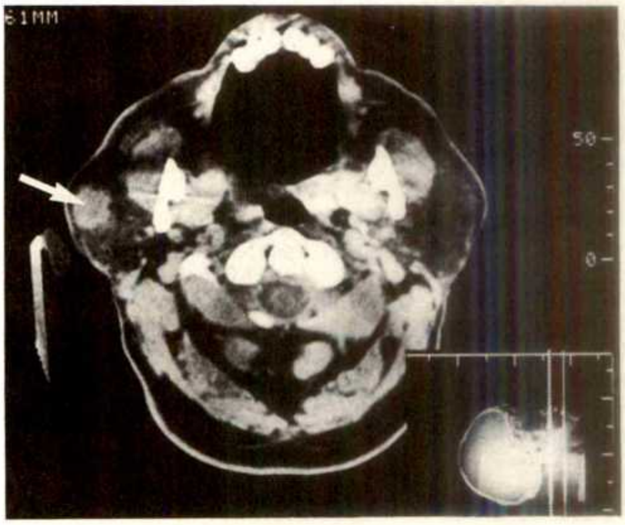

Figure 1 *Computed tomographic scan showing accurate delineation of a mass in the right superficial parotid (arrow)*

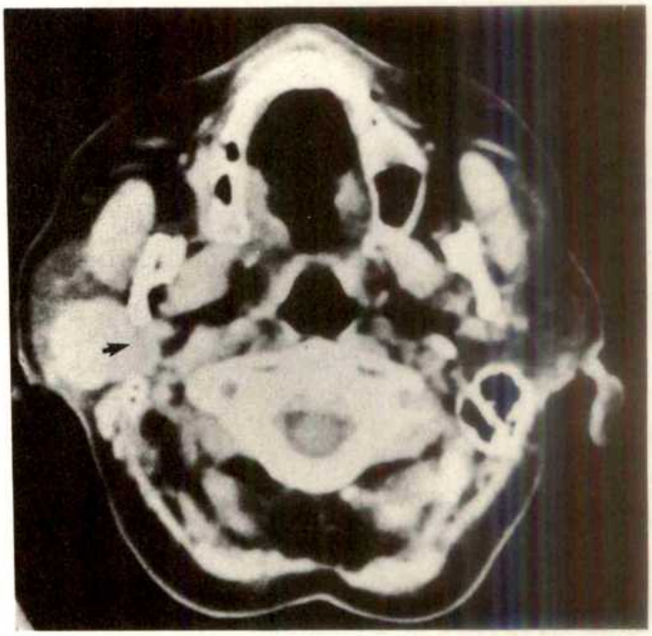

Figure 2 *Computed tomographic scan showing a superficial lesion with clear demonstration of deep extension into the parotid (arrow)*

Discussion

FNAC is a simple, inexpensive method for obtaining a tissue diagnosis and numerous reports in the literature demonstrate its accuracy[5,6]. Complications of FNAC of the parotid are infrequent, minor and transient. Haematoma and superficial infection are rarely seen and did not occur in this series. Dissemination of tumour cells or cell clusters via the needle track, efferent lymphatics or blood vessels with resultant

0007-1323/89/121273-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

extension of the neoplastic growth is a theoretical risk, but no published series, including the present study, have demonstrated this when a fine needle (18–22 gauge) is used with a single skin pass technique.

Eneroth *et al.*[7] and Lindberg and Akerman[8] in a series of 1860 salivary gland tumours had no recurrences following FNAC. Engzell *et al.*[9], in a retrospective analysis of 157 pleomorphic adenomas with a 10-year follow up, demonstrated three tumour recurrences following FNAC; two of these, however, were associated with incomplete excision of the primary tumour.

In the occasional case reports of growth along needle tracks, either a large calibre Vim-Silverman needle or multiple skin passes with a fine needle were used. However, follow-up in this series is too short as yet to be certain that there is no risk of implantation. A recent report of tumour implantation after FNAC of a colonic hepatic metastasis gave no details of the aspiration technique[10].

CT will show lesions extending outside an organ or arising in adjacent structures. This is a particular advantage with the parotid gland since it is a small structure and even primary lesions may be predominantly extraglandular[11]. CT provides precise anatomical detail showing the exact location of a mass within the gland. Pleomorphic adenomas are usually seen as a sharply defined mass with smooth borders (*Figure 1*). Furthermore, it is of great value to ascertain the size and extent of involvement of the gland, which is accurately demonstrated by this technique (*Figure 2*). The surgeon is thereby forewarned of the extent of the operation and the higher risks involved.

These two investigations will provide an accurate preoperative diagnosis of the histological type and anatomical site of a parotid mass, enabling the surgeon to select those tumours, such as adenolymphoma, which require local excision only, and to avoid operative intervention for inflammatory or secondary neoplastic conditions. This approach should reduce the complications of unnecessarily extensive procedures.

Management of high grade parotid carcinomas

Thirty-four patients admitted to the Bristol Royal Infirmary during the 20-year period 1966–85 and diagnosed as suffering from high grade parotid carcinoma were studied. The male:female ratio was 2·4:1, with a mean age at presentation of 68 years. Facial swelling was present in all patients with a mean duration of 9·9 months before treatment. Pain, deep fixation, facial nerve involvement, ulceration and distal metastases were all associated with a poor prognosis. Diagnosis was made either at operation or by fine needle biopsy. All 34 patients received radiotherapy. Fourteen patients (41 per cent) underwent a definitive surgical procedure. The local recurrence rates for the non-surgical and surgically treated groups were 30 per cent (six patients) and 36 per cent (five patients) respectively; twelve patients (60 per cent) in the non-surgical group developed distant metastases as opposed to six patients (43 per cent) in the surgical group. Both local and distant recurrent disease are indicators of poor prognosis, with only one patient alive at 104 months. Seven patients (21 per cent) remain recurrence free. Definitive surgery, combined with radiotherapy, improved survival in those with amenable localized disease.

Mr A. J. Webb

Parotid tumours account for 73 per cent of all salivary gland neoplasms, of which 15 per cent are malignant[1]. High grade parotid carcinomas include poorly differentiated adenocarcinoma, squamous cell carcinoma, undifferentiated carcinoma and carcinoma arising in pleomorphic adenomas[2]. This group of tumours is uncommon, comprising less than 7 per cent of all parotid neoplasms[1]. Their diagnosis and treatment remains controversial. Although the benefits of postoperative radiation therapy have been widely accepted[3–8], the initial diagnostic procedure together with the timing and extent of surgical excision is uncertain.

Since 1966, 34 patients with high grade parotid carcinoma have been treated at the Bristol Royal Infirmary. Of these, 14 received combined surgery and radiotherapy, whereas in 20, after an initial diagnostic biopsy, radiotherapy alone was employed. The purpose of this study is a retrospective comparison between the two treatment groups with respect to recurrent disease and subsequent survival.

Patients and methods

All patients diagnosed at the Bristol Royal Infirmary as suffering from high grade parotid carcinoma during a 20-year period, 1966–85, were identified from hospital records (diagnostic index and pathology files). In each case the diagnosis was confirmed by review of the original histological and cytological slides. Review of the histology revealed nine poorly differentiated adenocarcinomas, ten undifferentiated tumours, two carcinomas arising in pleomorphic adenomas, and one poorly differentiated squamous cell carcinoma. Cytological review added a further five poorly differentiated adenocarcinomas and seven undifferentiated tumours. All tumour types were grouped together as high grade parotid carcinomas for the purpose of data analysis.

Results

A total of 34 patients (24 men, 10 women, mean age 68·0 years, range 41–87 years) were identified. Of these, 16 of the tumours were on the left and 18 on the right.

Presenting symptoms (Table 1)

All patients presented with facial swelling (mean duration 9·9 months, range 2–48 months) and 13 complained of pain (mean duration 6·7 months, range 2–18 months). Thirty tumours demonstrated deep fixation, 15 lymph node involvement, and in ten 7th nerve palsy was evident. Distant metastases were present in seven and skin ulceration in five.

Initial diagnostic procedure

Parotidectomy without biopsy was performed in eight patients (superficial parotidectomy in six and total parotidectomy in two), whereas an open incision biopsy procedure was the diagnostic method in 14. Fine needle aspiration biopsy cytology was performed in 12.

Definitive surgical procedure

Of the 26 patients receiving initial tumour biopsy, six subsequently underwent further definitive surgery (three total parotidectomies, two superficial parotidectomies and one local excision). All 34 patients received radiotherapy; in addition, five patients accepted chemotherapy.

Survival analysis (Table 2)

To date, five patients are alive (mean 73·8 months, range 10–156 months) and 29 dead (mean 15 months, range 1–60 months). Seven patients have remained totally recurrence free, and four of these are still alive (mean 66·3 months, range 10–156 months). Three deaths were due to unrelated pathology (mean 26 months, range 10–35 months). Local recurrence occurred in eleven patients of whom only one is still alive at 104 months. The mean survival in this group was 18 months (range 6–29 months). Distant recurrence developed in 18 patients, all of whom died (mean 16·8 months, range 1–60 months).

Survival as function of treatment (Table 3)

Radiotherapy alone following initial biopsy procedure. In 20 patients there was no definitive surgical excision. Two remained recurrence free, one of whom is still alive at 58 months; the other died of unrelated disease at 10 months. Local recurrence occurred in six patients at a mean of 8·5 months (range 2–19 months). All in this group are now dead (mean 16·8 months, range 1–38 months). Distant recurrence occurred in 12 patients,

and all have subsequently died (mean 16·4 months, range 1–60 months).

Combined surgical excision and radiotherapy. Of these 14 patients, five remained recurrence free. Three are alive (mean 90 months, range 10–156 months) and two have died of unrelated disease (mean 34 months, range 33–35 months). Local recurrence developed in five patients (mean 14·6 months, range 1–60 months), four of whom are dead (mean 17·3 months, range 3–27 months), with a sole survivor at 104 months. Of the six patients who developed distant metastases, all died (mean 16·5 months, range 9–27 months).

A detailed analysis of surgical procedure related to recurrence rate and subsequent survival is given in *Table 3*. In addition to the above treatment, five patients received adjuvant chemotherapy. All of these are dead with a mean survival of

16·6 months (range 6–27 months). The mean survival of the non-chemotherapy patients is 16·25 months (range 1–60 months).

Discussion

Salivary tumours are most common in the parotid gland; consequently the majority of malignant salivary tumours are in this gland. Although surgical excision, with or without radiotherapy, remains the standard treatment for benign and well differentiated malignant parotid neoplasms, uncertainty exists regarding the treatment of high grade carcinomas. During the past decade there has been an inclination towards treatment by radiotherapy, after diagnosis by fine needle aspiration or an alternative biopsy technique[9].

Although several studies have reported the efficacy of surgery and radiotherapy in controlling local disease[3–5,7,8,10,11], its potential for prolonging life expectancy is unsure. Since all our patients received radiotherapy, the effect of surgery on the recurrence and survival rates can be assessed.

Some groups advocate radical surgery in all cases of parotid malignancy[5,12–14], although survival rates have not been improved[15,16]. A more conservative operative approach combined with radiotherapy is an alternative option[4,5,7,16].

Management of high grade parotid carcinomas is complicated by the paucity of cases and the relative lack of comparative data. A widely reported 5-year survival rate is 25 per cent, despite an aggressive surgical approach[17]. Since the morbidity following radical parotidectomy is itself high[5,17], a less extensive surgical approach is preferable, provided recurrence and mortality rates remain unchanged. At the Bristol Royal Infirmary, fine needle aspiration biopsy remains the investigation of choice in the diagnosis of malignant parotid lesions[18]. This investigation is very unlikely to result in tumour seeding[19]; in the present study no increased incidence of local recurrence is noted following incisional or needle biopsy, when compared with a definitive surgical approach.

Both local and distant recurrences are associated with a poor prognosis (*Table 2*). Of the 18 patients developing metastatic disease, all are now dead at a mean of 16·4 months and 16·5 months for the non-operative and operative groups respectively. Only one patient with local recurrence is still alive.

To date, seven patients (21 per cent) are free of recurrence. Recurrence of these high grade carcinomas in the parotid therefore carries a disastrous prognosis. These lesions are usually highly infiltrative, extending well beyond the primary site, and regardless of radical secondary surgery prognosis remains poor[8,20]. Definitive primary management is clearly important and should be tailored to the clinical state. Indicators of poor prognosis include pain, deep fixation, superficial ulceration, facial nerve involvement and distal metastases (*Table 1*).

From our study, it seems that definitive surgery is unlikely to influence survival and a more conservative approach would appear to be preferable. However, in the absence of the above prognostic indicators, surgical intervention can increase the mean survival, primarily owing to its effect in lowering the probability of developing locally recurrent disease (*Table 3*).

Despite the relatively large number of patients available for this study, the variety of different treatment regimens renders comparison imprecise. It is our impression that patients with localized or minimally invasive disease who are otherwise fit for surgery should receive it. Although the local recurrence rates remain unaffected, survival appears to be improved. We cannot confirm the view that radical as opposed to superficial parotidectomy is preferable, except perhaps for deep lobe involvement.

Since the results for advanced disease are so poor, a less radical approach, consisting of radiotherapy after fine needle aspiration biopsy diagnosis, may be a more rational treatment.

The value of fine needle aspiration biopsy in the early diagnosis of parotid neoplasms is emphasized. Early diagnosis of all parotid lesions is essential if the results of surgical management of this aggressive tumour are to be improved. The mean time delay of 9·9 months between the appearance of facial swelling and the diagnosis in the present series can surely be improved.

The importance of early diagnosis in all parotid swellings needs strong emphasis and swift referral to a specialist centre for salivary tumours is desirable. Fine needle aspiration biopsy may be performed very simply and definitive treatment may be planned according to the disease staging. The sensitivity of aspiration cytology for salivary carcinoma is high. For locally advanced disease with evidence of metastases at presentation, palliative radiotherapy alone after some form of biopsy is sufficient; no obvious advantage is to be gained from a major surgical procedure. It is suggested that management should be designed to match the stage of disease presentation: early diagnosis appears to offer the best chance of improving survival.

Mr N. E. Dudley

Whole body scintigraphy with [^{99m}Tc](v)dimercaptosuccinic acid (pentavalent DMSA) was performed in seven patients with histologically confirmed medullary carcinoma of the thyroid (MCT). Six of these patients had undergone previous thyroid resections for MCT and, although asymptomatic at the time of pentavalent DMSA scintigraphy, had persistent and serial elevations in their plasma calcitonin levels. One additional patient was scanned before and after total thyroidectomy for MCT. The pentavalent DMSA scintigram demonstrated either local neck recurrence (three patients) or distant metastases (two patients) in five of the six asymptomatic patients. In one asymptomatic patient only equivocal neck uptake was demonstrated. Since he had only minimal calcitonin elevations, repeat neck exploration was not performed. The one patient studied before thyroid resection for MCT demonstrated neck uptake before, but not after, total thyroidectomy. The results of the scintigrams had significant impact on patient care and resulted in neck re-exploration (three patients), neck biopsy (one patient), and lumbar spine biopsy and subsequent radiotherapy (one patient). These data demonstrate pentavalent DMSA to be a sensitive localizing agent in the evaluation of asymptomatic MCT patients with hypercalcitonaemia. Accurate targeting of treatment may be shown in due course to have a beneficial impact on survival.

Keywords: Medullary carcinoma of the thyroid, [^{99m}Tc](v)dimercaptosuccinic acid, hypercalcitonaemia, Sipple syndrome

Medullary carcinoma of the thyroid (MCT) was first described as a distinct clinical entity by Hazard *et al.*[1] in 1958. This solid tumour behaved as an intermediate thyroid malignancy in terms of its aggressiveness, with the propensity for local lymph node metastasis, distant metastasis and an indolent course. The familial occurrence of thyroid carcinoma in association with phaeochromocytoma was subsequently recognized by Sipple and the multiple endocrine neoplasia (MEN 2a) syndrome was described[2]. MCT has been of particular oncological interest because this tumour, which arises from the parafollicular cells, secretes the specific tumour marker calcitonin. Calcitonin screening in MEN kindreds has resulted in the early diagnosis and treatment of MCT in affected family members[3].

The surgical approach to patients with MCT is generally a total thyroidectomy[4–6] and removal of nodes in the primary lymphatic drainage area. Although most patients demonstrate a marked diminution in their postoperative calcitonin levels, a significant subset of patients have persistent postoperative hypercalcitonaemia. Faced with the clinical dilemma of recommending therapy for these asymptomatic post-thyroidectomy patients who had persistent and serial elevations in their calcitonin levels, we sought the use of radiopharmaceuticals that were reported to have high sensitivity and specificity for MCT. Initial enthusiasm for iodine-131 metaiodobenzylguanidine ([^{131}I]MIBG)[7–9] was tempered by a series of articles reporting equivocal results[10–13]. Therefore we used a modified isotope complex, pentavalent DMSA ([^{99m}Tc](v)dimercaptosuccinic acid), which has been recently reported by three groups to have encouraging sensitivity for MCT[14–16]. In this paper we describe the efficacy and clinical utility of [^{99m}Tc](v)DMSA as a localizing agent in six asymptomatic patients with persistent hypercalcaemia after thyroid resection for MCT. An additional case in which we performed scintigraphy both before and after total thyroidectomy for MCT is also presented.

Patients and methods

Seven patients with histologically confirmed MCT were selected for study (*Table 1*). Six of the patients were asymptomatic, but had persistent and serial elevations in their plasma calcitonin levels after undergoing either total thyroidectomy (five patients) or thyroid lobectomy (one patient) (*Figure 1*). One patient had MCT diagnosed preoperatively by a fine needle aspirate of a thyroid nodule. All patients underwent pentavalent DMSA scintigraphy in an attempt to localize their source of calcitonin production.

[^{99m}Tc](v)DMSA was prepared according to the method of Sampson[17]. Briefly, 4 mg DMSA, 120 mg dextrose and 5 mg sodium bicarbonate were added to a standard vial of DMSA (Amersham International plc, Buckinghamshire, UK) and the mixture was dissolved in 0·4 ml of 7 per cent w/v sodium bicarbonate solution. About 600 MBq [^{99m}Tc] pertechnetate was made up to 2·5 ml with normal saline and added to 0·1 ml of the DMSA solution in a mixing vial. The mixture was then passed through a 0·22 mm filter and 370 MBq of the filtered solution were injected within 1 h of preparation. Thin layer chromatography was used to assess the production of pentavalent DMSA.

Blood pool images were acquired 10 min after injection and whole-body planar scintigraphy was performed 2 h later using a General Electric Maxicamera 400 T (IGE Medical Systems Ltd., Slough, UK) fitted with a low-energy high-resolution collimator and interfaced to a computer with data display facilities. 550 000 counts were obtained per image. The appearance of isolated photon-abundant areas (hot spots) in the 2-h scintigrams were taken to indicate the presence of metastatic MCT.

0007-1323/89/121278-04$3.00 © 1989 Butterworth & Co (Publishers) Ltd

Calcitonin was measured by radioimmunoassay in rapidly frozen plasma samples. The normal range is <0·08 ng/ml with an intra- and inter-assay variation of 9 and 13 per cent, respectively.

All pathological material was reviewed by a single pathologist and the diagnosis of MCT was verified in every case.

Case reports

The following case reports are summarised in *Table 1*.

Case 1. A 53-year-old woman underwent left total thyroid lobectomy for a painless left neck mass. The specimen contained MCT with extensive capsular and vascular invasion. The right lobe and isthmus were removed 2 weeks later, but there was no evidence of MCT or C cell hyperplasia in the specimen. Her initial postoperative calcitonin level of 0·1 ng/ml was monitored and had risen to 0·28 ng/ml 3 years later. It then rose steeply over the next year to a peak of 2·13 ng/ml. She remained asymptomatic. A pentavalent DMSA scintigram demonstrated uptake in her lumbar spine (*Figure 1a*). A computed tomography (CT) scan confirmed a lytic lesion in the body of L3 (*Figure 1b*) and she rapidly developed diarrhoea and back pain. A bone biopsy confirmed metastatic MCT and whilst undergoing palliative radiotherapy the affected lumbar vertebra started to collapse requiring internal fixation. The calcitonin level has ceased to rise and is currently stable at 2·01 ng/ml.

Case 2. A 48-year-old woman underwent left thyroid lobectomy and a frozen section was highly suggestive of MCT. A total thyroidectomy was performed. A single focus of MCT was verified in the left thyroid lobe. A postoperative thyroid scan demonstrated no residual thyroid tissue. She remained asymptomatic but serial calcitonin levels began to rise 5 years later to a peak of 1·13 ng/ml 6 years after operation. A pentavalent DMSA scintigram demonstrated increased uptake in the anterior neck (*Figure 2*). In spite of the fact that the tumour was evident on neither clinical examination nor CT

scan she underwent repeat cervical exploration. A palpable nodule containing metastatic MCT was found at operation in an anterior mediastinal lymph node, having been accurately localized before operation. Following removal of this the calcitonin level fell to <0·1 ng/ml.

Case 3. A 20-year-old man was noted to have a mediastinal mass on routine chest radiograph. Biopsies of enlarged right cervical and supraclavicular lymph nodes were initially interpreted as a malignant teratoma. He was referred to the John Radcliffe Hospital after he failed to respond to three courses of chemotherapy. Review of the original specimen revealed metastatic medullary carcinoma. He underwent total thyroidectomy with right modified radical neck dissection. The specimen revealed the primary focus of MCT confined to the right thyroid lobe with metastatic MCT in multiple right cervical and anterior mediastinal lymph nodes. Because of the presence of mediastinal and isolated left pulmonary metastasis he subsequently underwent left pneumonectomy and clearance of mediastinal lymph nodes. He did well postoperatively but had persistent and very high calcitonin levels (>40 ng/ml). A pentavalent DMSA scintigram demonstrated increased uptake in the mediastinum (*Figure 3*). This recurrent tumour mass has been deemed unresectable.

Case 4. This 42-year-old woman developed profuse diarrhoea with an associated 9 kg weight loss and was noted to have a left thyroid mass. A fine needle aspirate of the mass revealed MCT. Her preoperative calcitonin level was 1·89 ng/ml. A preoperative pentavalent DMSA scintigram suggested uptake in both thyroid lobes with possible uptake in the anterior mediastinum. A CT scan of the neck confirmed thyroid nodules but did not demonstrate an abnormal mediastinal mass. She underwent total thyroidectomy and cervical thymectomy. Histological review revealed two separate foci of MCT in the left thyroid lobe, diffuse nodular hyperplasia and an atrophic thymus without evidence of MCT. Her postoperative pentavalent DMSA scintigram revealed no uptake in the neck or mediastinum. Her diarrhoea resolved and the calcitonin level fell to 0·05 ng/ml.

Case 5. This 45-year-old woman underwent right thyroid lobectomy for a gradually enlarging right thyroid mass. The contralateral lobe appeared normal and there was no evidence of lymph node metastasis. A 10 × 10 cm encapsulated nodule was noted on permanent section to be diagnostic of MCT. Her postoperative course was uneventful. Her postoperative calcitonin level was elevated to 0·19 ng/ml. Pentavalent DMSA scintigraphy demonstrated a single focus of increased activity in the right anterior neck. She underwent repeat neck exploration with resection of a small residual amount of her right thyroid lobe resulting in a total thyroidectomy plus clearance of adjacent palpable enlarged lymph nodes alongside the thyroid and in the anterior mediastinum. The resected specimen revealed metastatic MCT in these nodes, which again corresponded to the site of increased activity on the scintigram. The calcitonin level in this patient has remained elevated at 0·20 ng/ml but a repeat pentavalent DMSA scintigram shows no hot spot such as was previously seen.

Case 6. This 25-year-old man was first noted to have recurrent episodes of chest pain and headaches. He did well until 1964 when he underwent a right cervical sympathectomy for Reynaud's phenomenon. During the course of the procedure he developed a rapid tachycardia and a subsequent evaluation confirmed the presence of a phaeochromocytoma. Accordingly, he underwent an abdominal exploration and a right phaeochromocytoma was removed. The left adrenal gland appeared normal. He was followed closely and in 1964 a mass was noted in the left thyroid lobe. Cervical exploration confirmed a mass in the upper left thyroid lobe and a left thyroid lobectomy was performed. In addition a parathyroid adenoma was removed. Pathological review confirmed both a well encapsulated medullary carcinoma in the thyroid and a parathyroid adenoma. The MEN 2a syndrome had by then been described as a distinct clinical entity and was clearly identified in this patient. He remained well until 1968 when metastatic disease was recognized in the left posterior triangle of the neck and he underwent a modified block dissection and subsequent postoperative radiotherapy.

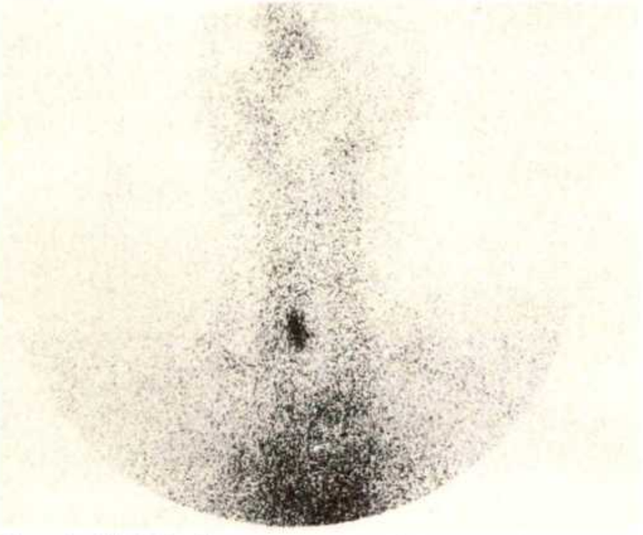

Figure 2 *[^{99m}Tc](V)dimercaptosuccinic acid scintigram demonstrating increased uptake in the lower right neck in case 2*

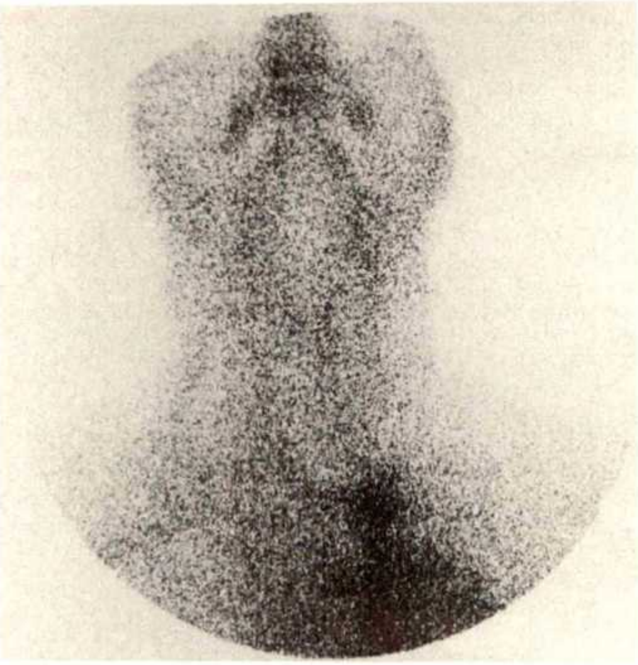

Figure 3 *Computer-enhanced [^{99m}Tc](V)dimercaptosuccinic acid scintigram demonstrating increased uptake in the right anterior neck in case 3*

In 1978 symptoms prompted a transurethral prostatectomy and he was noted to have marked hypertension during anaesthesia. A phaeochromocytoma could not be confirmed, however, until 1980 at which time he underwent left adrenalectomy.

His family history is positive for MEN 2a syndrome in a sister, nephew and two sons. His father died of 'renal disease' at age 79.

He remained asymptomatic but his calcitonin levels were persistently elevated.

A pentavalent DMSA scintigram demonstrated increased activity near the midline in the lower half of the right neck and a fine needle aspirate of the area corresponding to the right thyroid lobe has confirmed MCT. This patient awaits surgical exploration.

Case 7. This 20-year-old son of the patient in case 6 was noted to have the MEN 2a syndrome. He underwent total thyroidectomy and was noted to have MCT in both thyroid lobes. On postoperative screening, his calcitonin level was mildly elevated to 0·13 ng/ml. A pentavalent DMSA scintigram suggested increased uptake in the anterior neck. Since he has minimal calcitonin elevations, is asymptomatic and has an equivocal scintigram, repeat neck exploration was deferred pending the results of additional calcitonin tests and serial scintigraphy.

Discussion

There is broad agreement that in patients with hereditary and sporadic MCT an adequate initial cervical operation removing all thyroid tissue and lymph nodes in the primary lymphatic drainage area of the gland is required[6]. Suspicious nodes beyond the primary lymphatic drainage areas should also be dissected out.

Over the years that this strategy has evolved some patients who have and some who have not undergone such extensive surgery remain normocalcitonaemic. The expectation is that they will continue to have a good prognosis. Where initial surgery has been adequate yet local recurrence is clearly evident, then in many cases, if justified by the patient's general state of health, further surgery to reduce the tumour burden should be attempted. Although cure is then unlikely and calcitonin levels rarely return to normal, the patient can be expected to obtain worthwhile palliation. A more difficult management problem arises when a patient being followed up after adequate primary surgery for MCT shows a serial rise in plasma calcitonin, yet in whom no local recurrence or distant metastases can be demonstrated on thorough clinical examination or conventional screening. This was the situation pertaining to all cases excepting case 4 in this series. One option would have been to try to localize the source of the calcitonin production by selective venous sampling after pentagastrin stimulation – a procedure adopted with success in seven patients by Norton *et al.*[18]. However, this technique is invasive, time consuming, labour intensive and therefore expensive. Recurrent disease will be detected only if the vein draining the location is sampled, and this is unlikely to happen when a metastatis occurs in an unexpected site, as for example, in case 1 reported here. A scanning technique that facilitates identification of substantial MCT after surgery (or ideally residual disease intraoperatively) would enable the surgical strategy outlined earlier to be more effectively implemented. It was this prospect that prompted the evaluation of pentavalent DMSA scintigraphy, the experience of which to date has been limited and variable. Ohta *et al.* described four MCT patients with hypercalcitonaemia and significant tracer uptake in palpable cervical tumour and metastatic sites[14]. Although encouraging, all of these patients had bulk disease that was evident on clinical examination or conventional radiological studies. Subsequently, Hilditch *et al.* reported no uptake in any of five patients with hypercalcitonaemia[11]. This report is of particular interest because these patients were thought to have early disease with only modest calcitonin levels – the subset of patients in whom a sensitive early scintigraphic technique would have the greatest impact. The failure of these patients to concentrate pentavalent DMSA may have been due to either lack of assay sensitivity or, as suggested by Endo *et al.*[19] and Clarke *et al.*[20], technical problems with isotope preparation. More recent reports by Ramamoorthy *et al.*[15] and Clarke *et al.*[16] have been more favourable. However, all of the patients reported by Ramamoorthy *et al.* appeared to have had known metastasis, and seven of the ten patients reported by Clarke *et al.* were symptomatic at the time of study, suggesting advanced disease. In a subsequent publication, Clarke *et al.* compared the use of [^{99m}Tc](v)DMSA, [^{131}I] MIBG and [^{99m}Tc]MDP in these previously reported patients and concluded that DMSA was clearly superior[13].

Our experience with pentavalent DMSA has been particularly encouraging. In this series it has detected recurrence of MCT with sufficient accuracy to enable: further surgery to be directed to a specific site with confirmation of macroscopic disease in soft tissue (cases 2 and 5); a bone biopsy to be undertaken for an occult symptomless skeletal metastasis with histological confirmation (case 1); and a fine needle aspiration sample to be taken from an area previously deemed to be blameless with the demonstration of C cells (case 6).

No case is made in this paper for surgical intervention just on the basis of hypercalcitonaemia. Where the calcitonin is modestly elevated and stable, it is probable that the patient has microscopic residual disease which will not advance rapidly. That was the conclusion of Cance[21] and of Block *et al.*[22], the latter group operating on eight of 18 such patients and finding micrometastases in all. A normal calcitonin level was achieved in only two patients and of the remainder 12 showed stable calcitonin levels over an average of nearly 4 years. Despite the fact that significant rises in calcitonin occurred in two patients (11 per cent), extensive reoperative surgery (duration 8–12 h) as described by Tisell *et al.*[23] without any attempt to localize disease first seems hard to justify. Targeted surgery or radiotherapy, shown to be possible by pentavalent DMSA scintigraphy, is likely to have a much lower morbidity and may have a significant benefit for patients who are observed to have a rising level of plasma calcitonin.

Dr G. Sonnenfeld

Tumour necrosis factor α and interferon γ have both been shown to have immunoregulatory properties, and to be able to influence several microbial infections. This study showed that tumour necrosis factor was effective in modifying surgically simulated wound infections when administered both as prophylaxis and as therapy. Two models were used; one was an intramuscular bacterial challenge, and the other involved the use of a bacteria-laden thigh suture. The test bacterium for both models was Klebsiella pneumoniae, *a common surgical pathogen in our surgical service. Interferon γ was an effective biological response modifier in these models. Tumour necrosis factor was more potent than interferon γ and there was no additive or synergistic effect with interferon γ. This indicates potentially different mechanisms of action for these two cytokines.*

Keywords: Tumour necrosis factor α, interferon γ, *Klebsiella pneumoniae*, wound infection

Infection, usually occurring within the surgical wound, remains the most common postoperative complication[1]. In recent years, the principal methods of reducing wound infection rates have been to keep operative bacterial contamination of the wound to a minimum, and to prevent those organisms which do lodge in the wound from proliferating by the judicious use of prophylactic antibiotics and antiseptics[2–4]. However, antibiotics, sterile techniques and mechanical barriers have all been shown to be incompletely effective. Thus, non-specific enhancement of host defence mechanisms has the potential further to improve infection control. One possible biological response modifier that could be used for such a purpose is tumour necrosis factor α (TNF).

TNF has been shown to have several immunoregulatory activities[5,6]. These include regulation of histocompatibility antigen expression in fibroblasts[7] and of interleukin 1 production and activity[8]. Therefore, TNF could play a major role in regulation of immune response. Human TNF has been shown to be active in murine systems[5–8]. Interferon γ (IFN-γ) is another immunoregulatory cytokine which has also been shown to regulate several immune responses[9]. In addition, IFN-γ has recently been shown to modulate resistance to bacterial infections in several models of infection[10–12], perhaps as a result of its immunomodulatory properties.

The present study was carried out to determine whether TNF also could affect resistance to infection in surgical wound infection models. Two well characterized models were used. One was an intramuscular bacterial challenge. The second involved use of a bacterium-laden thigh suture which combined the clinically relevant elements of pathogenic bacteria, tissue damage and a surgical foreign body[12,13]. The test bacterium was *Klebsiella pneumoniae*, a common surgical pathogen in our surgical service.

The experiments were designed to determine whether pretreatment with TNF could have a prophylactic effect on the course of infection. Additional experiments were carried out to determine whether TNF therapy could affect an established infection. Human TNF and murine IFN-γ have been shown to act synergistically in the killing of tumour cells[7,8]. For this reason, additional experiments were carried out to determine whether a combination of TNF and IFN-γ therapy is more effective than TNF treatment alone.

Materials and methods

Experimental animals

Adult male CBA/J mice (H-2^k) weighing 20–25 g each, supplied by Jackson Laboratories (Bar Harbor, Maine, USA) were used. The animals were maintained according to AAALAC (American Association for the Accreditition of Laboratory Animal Care) standards. They were deprived of food but allowed free access to water for 24 h before bacterial challenge and were fed 4 h following that challenge[14]. Studies were performed according to National Institutes of Health guidelines under the supervision of a veterinary surgeon.

Wound infection model

The bacterium used throughout these experiments was an encapsulated strain of *K. pneumoniae* (Capsular Type II) obtained as a gift from the Institut Pasteur (Reference Strain no. 7832)[15].

Two murine models of wound infection were used.

Intramuscular challenge. K. pneumoniae was administered by 0·1 ml intramuscular injection into the right hind limb (approximately 10^3 bacteria: range 9×10^2 to $2·5 \times 10^3$ bacteria)

Thigh suture model Lengths of 3–0 blue twisted cotton suture were incubated overnight in trypticase soy broth (BBL Microbiological Systems, Cockeysville, Maryland, USA) inoculated with *K. pneumoniae* Lengths of suture attached to a French eye needle were inserted aseptically into the right thigh of the mice and the suture was cut flush with the skin at both ends.

Tumour necrosis factor

Human TNF, produced by recombinant DNA technology, was a gift from Genentech Inc. (S. San Francisco, California, USA). The TNF had specific activity of approximately 5×10^7 units/mg protein and was certified as endotoxin free, confirmed by limulus amoebocyte lysate testing (Associates of Cape Cod Inc., Woods Hole, Massachusetts, USA). The endotoxin concentration was determined to be <0·03 endotoxin units/ml with no inhibition. TNF was diluted with RPMI-1640 medium (Rosewell Park Memorial Institute, Gibco Laboratories, Grand Island, New York, USA).

In one experiment, a dose response was determined using TNF administered in daily doses in 0·1 ml subcutaneous injections into the left hind limb In all other experiments TNF was administered in daily doses of 7500 units in 0·1 ml subcutaneous injections into the left hind limb In all experiments, control animals received 0·1 ml of RPMI-1640 medium subcutaneously at the same time as TNF was administered.

Interferon

Recombinant murine interferon γ was used in the *in vivo* experiments and was a gift from Genentech, Inc The IFN-γ had specific activity of approximately $2 \cdot 3 \times 10^7$ units/mg protein and was diluted with RPMI-1640 medium. The interferon was titred in our laboratory by means of a microplaque reduction assay using the Indiana strain of vesicular stomatitis virus on L-929 cells[16]. In this assay, one interferon unit was equivalent to 0 88 NIH G-002-904-511 reference standard units. IFN-γ was certified as endotoxin free, and independent limulus amoebocyte lysate testing confirmed that the endotoxin concentration was $<0 \cdot 06$ endotoxin units/ml with no inhibition. IFN-γ was administered in daily subcutaneous injections (7500 units in 0·1 ml) into the right hind limb. We have previously shown that IFN-γ is equally effective if administered in the same or opposite leg as the bacterial challenge[11].

Experimental design

Two experiments assessed the effect of TNF when administered for 5 days before intramuscular challenge. In the first experiment, survival of a TNF pretreated group ($n=10$) was compared with survival of a control group ($n=10$). The second experiment assessed the effect of TNF pretreatment in combination with IFN-γ. Four groups of 16 mice were studied, each pretreated for 5 days as follows: TNF, IFN-γ, TNF+IFN-γ, and RPMI-1640 medium (control)

Two experiments assessed the protective effect of TNF as therapy without pretreatment. In one, TNF treatment commenced 1 h after intramuscular challenge and was administered for 7 days. Survival of the TNF treated group ($n=32$) was compared with survival of a control group ($n=32$). The other experiment assessed the effect of TNF therapy in combination with IFN-γ therapy. We have demonstrated previously a modest but significant effect of IFN-γ therapy in this model[11]. Four groups of 20 mice, each treated as follows, were studied: TNF, IFN-γ, TNF+IFN-γ, and a control group

The next two experiments used the thigh suture model. In the first experiment, TNF or RPMI-1640 was administered daily for 5 days before suture challenge. Survival of a TNF group ($n=16$) was compared with survival of a control group ($n=16$). In the second experiment, TNF was administered as therapy without pretreatment. Treatment commenced 1 h after suture challenge and was administered for 7 days. Survival of a TNF group ($n=20$) was compared with survival of a control group ($n=20$). All surviving mice were observed for a minimum of 3 weeks after suture challenge to assess late mortality. These have been shown previously to be the most effective protocols for immunomodulation using this model[12]

In an experiment designed to assess the effect of TNF on local and systemic bacterial recovery following suture challenge, a TNF group ($n=30$) was compared with a control group ($n=40$). All mice were pretreated for 5 days before suture challenge. Eight animals from each group were killed by cervical dislocation at three time periods. 1, 2 and 3 days after suture challenge. Immediately after each animal was killed, blood was withdrawn by cardiac puncture into heparinized syringes. The medial compartment musculature, including the inserted suture, was excised *en bloc*, the suture dissected out, and its length measured with a micrometer. Blood and muscle then underwent quantitative bacteriology. The number of mice that died during the experiment was recorded.

Quantitative bacteriology

To estimate the initial bacterial inoculum, the number of bacteria per millimetre of suture was determined by homogenizing a 1 cm length of the suture with 10 ml of sterile phosphate buffered saline (PBS), using a glass mortar and an electrically driven Teflon® (Du Pont) pestle After agitation for 5 min, the homogenate was serially diluted in PBS, plated on nutrient agar (BBL Microbiology Systems, Cockeysville, Maryland, USA), incubated overnight at 37°C, and the bacterial colonies counted. The number of bacteria introduced initially into an animal was calculated from suture length Quantitative determination of the number of bacteria in the wound was performed in a similar manner. Each excised specimen of muscle, together with the inoculating suture, was homogenized and plated as above. These values are presented as a percentage of local bacterial recovery from muscle, expressed on a $\log_{10}$ scale. Blood removed by cardiac puncture (0·1 ml) was diluted serially with PBS and plated on nutrient agar. After overnight incubation, the number of colony-forming units was counted, allowing accurate assay of bacteraemia. Blood bacterial counts were expressed on a $\log_{10}$ scale.

Endogenous cytokine production

Spleen cells were removed from mice 48 h after commencement of infection in both the intramuscular and surgical wound infection models. The spleen cells were teased into individual cell cultures and placed in RPMI-1640 medium, and 5 μg/ml of phytohaemagglutinin-P was added to each culture, after which they were allowed to incubate at 37°C for 24 h. The culture supernatant fluids were harvested and assayed for cytokine activity. TNF activity was determined on L-929 cells by the method of Ruff and Gifford[17]. IFN-γ activity was determined by the microplaque reduction method of Campbell *et al*[18] using L-929 cells and the Indiana strain of vesicular stomatitis virus. In this assay, one IFN unit was equivalent to 0 88 NIH G-002-904-511 reference standard units.

Statistical analysis

Data are expressed as mean and standard error of the mean Student's *t* test for independent means was used for muscle and blood culture results. The χ^2 test with Yates' correction for continuity was used for survival data. Fisher's exact test was used if the expected value in any cell was <5. In all cases, differences were considered significant at $P<0 \cdot 05$.

Results

Effect of 5 days pretreatment with TNF on the course of intramuscular K. pneumoniae *infections in mice*

When mice were pretreated with 7500 units of TNF daily, they survived significantly longer than controls. Higher (750 000 units) or lower (750 units) doses of TNF were not as effective in prolonging survival (*Figure 1*). Seven in the TNF group survived compared with one in the control group ($P<0 \cdot 05$).

In the experiment assessing the effect of the combination of

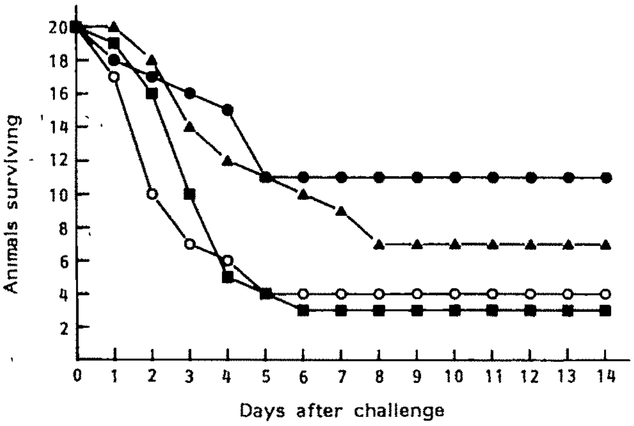

Figure 1 *Dose–response study of survival of mice treated with tumour necrosis factor (TNF) for 5 days before intramuscular* K. pneumoniae *challenge.* ○, *controls;* ■, *750 units TNF/day;* ●, *7500 units TNF/day,* ▲, *750 000 units TNF/day*

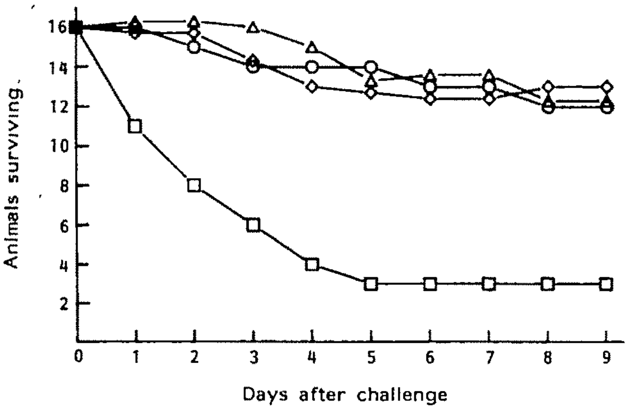

Figure 2 *Survival of mice treated with tumour necrosis factor (TNF) and/or interferon γ (IFN-γ) for 5 days before intramuscular* K. pneunoniae *challenge ncompared with controls* □, *controls;* △, *TNF,* ○, *IFN-γ,* ◇, *TNF+IFN-γ. TNF, IFN-γ and TNF+IFN-γ groups had significantly improved survival compared with controls at each day after bacterial challenge*

TNF and IFN-γ administered as a pretreatment, the TNF, IFN-γ, and TNF + IFN-γ groups all had significantly improved survival over the control group for each day after bacterial challenge (*Figure 2*). Their effects were similar. Analogous enhanced survival was observed when murine TNF was used (data not shown).

Effect of TNF therapy on course of intramuscular K. pneumoniae *infections in mice*

When treatment was started 1 h after infection, survival was markedly greater in the TNF group than in the control group from day 3 onwards. After day 6, 18 of 32 mice in the TNF group and 6 of 32 mice in the control group survived ($P < 0.05$)

In the experiment assessing the effect of the combination of TNF and IFN-γ administered as therapy, survival in both the TNF and TNF + IFN-γ groups was significantly greater than in the control group (*Figure 3*). More mice in the IFN-γ group survived than in the control group, but this difference was not statistically significant.

Effect of TNF on survival after suture challenge

The intramuscular dose of *K. pneumoniae* introduced with the sutures ranged between $2{\cdot}1 \times 10^6$ and $4{\cdot}6 \times 10^6$ organisms. In the experiment with 5 days of TNF pretreatment, the pretreated group had a survival rate that was appreciably greater than the control group from day 4 onwards. There were no further deaths after day 7. Eleven mice in the TNF group survived compared with only 3 in the control group.

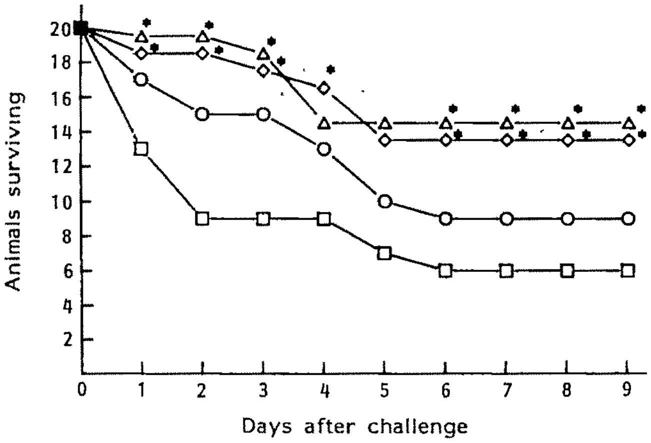

Figure 3 *Survival of mice treated with tumour necrosis factor (TNF), and/or interferon γ (IFN-γ) compared with controls, when treatment commenced 1 h after* K. pneumoniae *intramuscular challenge and continued daily for 7 days.* □, *control;* △, *TNF,* ○, *IFN-γ,* ◇, *TNF+IFN-γ,* *, *statistically significant difference from control*

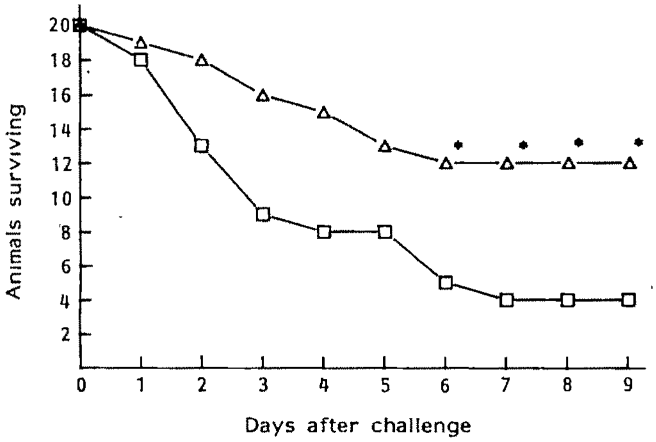

Figure 4 *Survival of mice treated with RPMI-1640 medium (controls) or tumour necrosis factor (TNF) daily for 7 days commencing 1 h after suture challenge.* □, *control;* △, *TNF;* *, *statistically significant difference from control*

Table 1 *Number of animals killed for quantitative cultures and mortality at each time period*

Time period	Mortality	Control group (n=40)	Tumour necrosis factor treated group (n=30)
Day 1	Killed	8	8
	Died	7	3
Day 2	Killed	8	8
	Died	5	2
Day 3	Killed	6	8
	Died	6	1

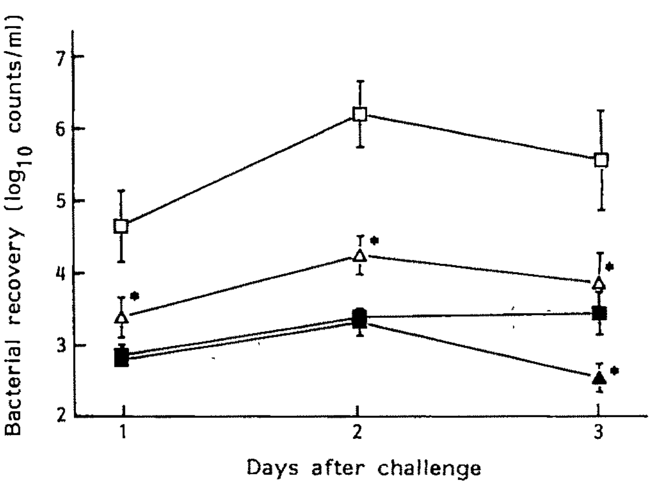

Figure 5 *Effect of tumour necrosis factor (TNF) pretreatment on systemic and local bacterial recovery from mice following suture challenge systemic recovery. Systemic recovery;* □, *control;* △, *TNF Local recovery* ■, *control;* ▲, *TNF. Error bars refer to standard error of the mean*

In the TNF therapy experiment with no pretreatment, the TNF group survived to a significantly greater extent than did the control group from day 6 onwards (*Figure 4*). There were no further deaths after day 7, and 12 mice in the TNF group survived compared with only four in the control group ($P < 0.05$).

Effect of TNF on quantitative bacterial counts after suture challenge

The number of animals killed for quantitative bacteriology is shown in *Table 1* The TNF pretreated group consistently had significantly lower systemic blood-borne bacterial counts than the control group (*Figure 5*). There was no difference in local bacterial recovery at the site of infection between the TNF pretreated group and the control group at days 1 and 2 after suture challenge. However, the TNF-pretreated group had markedly less local bacterial recovery than the control group 3 days after challenge

Production of IFN-γ and TNF by mice during models of wound infection

Control mouse spleens challenged with phytohaemagglutinin showed mean production of 7 units of IFN-γ and 6 units of TNF. Spleen cells from mice maintained in the intramuscular infection model showed no detectable IFN-γ production and 2 units of TNF. Spleen cells from mice maintained in the thigh suture infection model showed no detectable IFN-γ production and 4 units of TNF.

Discussion

TNF has been shown to have several immunoregulatory properties[5,6], which make it a good candidate for use in determining the ability of cytokines to modulate microbial infections. In this study, two well established models of surgical wound infection were used[11,12,14]. The thigh suture model combines the clinically important elements of pathogenic bacteria, foreign body and tissue damage[12,13,14].

The results of this study indicate that pretreatment of mice with TNF for 5 days before intramuscular infection with *K. pneumoniae* resulted in enhanced survival of those mice compared with controls. Similar effects were seen in the thigh suture model in which mice pretreated with the same regimen of TNF had significantly improved survival compared with controls. This is in agreement with previously reported work from Parant and coworkers[15,16], which indicated that both crude and pure preparations of TNF resulted in protection in mice from *K. pneumoniae*, as well as from several other bacterial and fungal infections[19].

It would also appear that TNF is protective even when given after initiation of bacterial infection. When TNF was administered therapeutically after bacterial inoculation, survival of mice was enhanced appreciably compared with controls, in both the intramuscular challenge and the thigh suture models. However, neither model showed an enhancement of survival with TNF therapy as great as that demonstrated when TNF was administered as a pretreatment. Nevertheless, the fact that TNF therapy was effective might ultimately prove to be of importance if TNF can be shown to be safe and to give consistently reproducible results. Previous studies with IFN-γ have indicated a limited protective effect in the 1 h therapy in *K. pneumoniae* model, and TNF may be more effective than IFN-γ[11]. Selection of an appropriate dose of TNF is crucial. In this study a low dose of TNF was selected because of the known detrimental effects of high doses[20]. Indeed, TNF may be one of the endogenous mediators of septic shock[20]. In murine models of septic shock, in which high circulating levels of endogenous TNF are present, the administration of polyclonal antisera directed against TNF actually improved survival[21]. Thus, it would appear that TNF has a narrow therapeutic index. In the animal models used in this study, a 100-fold increase in TNF dosage resulted in toxic effects.

Using the thigh suture model, it was possible to determine the effect of cytokine treatment on systemic and local bacterial recovery in addition to its effect on survival[12,13,14]. Earlier studies have indicated that IFN-γ pretreatment of mice before thigh suture resulted in decreased mortality[12]. In addition, counts of blood-borne bacteria, but not bacteria isolated from the wound site, were decreased in IFN-γ treated mice[11]. This study showed that bacterial recovery from the blood of TNF-pretreated mice was decreased significantly compared with controls. Bacterial recovery from local wound sites was reduced significantly on the third day after suture challenge in TNF-pretreated mice. This suggests that TNF has both local and systemic effects on bacterial recovery, in contrast with previous reports on IFN-γ, and suggests that it has a different mechanism of action from IFN-γ.

Previous reports have suggested a synergistic effect of TNF and IFN-γ when both were used in tumour models[5,6]. Potentially synergistic or additive effects of TNF and IFN-γ were examined in the intramuscular challenge model. When mice were pretreated with cytokines for 5 days before infection, survival was enhanced markedly in mice pretreated with INF-γ compared with controls. Mice pretreated with TNF or the combination of TNF and IFN-γ also had a significantly improved survival compared with controls. There was no difference in survival of mice between the three cytokine treatment groups at any time. Although synergy between TNF and IFN-γ was not demonstrated, survival was so dramatically improved in all three cytokine treatment groups that it may have been impossible to demonstrate synergy in this experiment.

When the cytokines were administered solely as therapy, commencing 1 h after bacterial challenge, there was a trend toward enhanced survival in the IFN-γ therapy group, as previously reported[11]. In the present study this trend did not reach the statistically significant levels seen in the previous study[11], perhaps as a result of the sample size used. Both the TNF group and the TNF+IFN-γ combination group had appreciably enhanced survival. There was no difference in survival between the TNF group and the TNF+IFN-γ combination group. Again no synergistic effect between TNF and IFN-γ was shown.

The results of this study demonstrate that TNF is a very effective immunomodulator in models of surgical wound sepsis at doses far below those inducing toxic effects[22–25]. The dose of 7500 units of TNF (6 μg/kg) is below both the dose noted by Schirmer *et al.* (1 mg/kg) not to affect cardiac output, heart rate or renal blood flow in rats[21], and the dose (0·6 mg/kg) used by Tracey *et al.* that resulted in tachypnoea, hypotension and 36 per cent mortality rate in rats[22]. The fact that TNF was effective when administered as therapy, commencing after bacterial challenge, is especially encouraging. In addition, endogenous TNF and IFN-γ production appears to have been compromised during these experiments in surgical wound infection. TNF, therefore, may have the potential to enhance the immune response in infected patients and may be helpful when bacterial infection is refractory to antibiotic therapy.

★ Second edition of this classic systematic and comprehensive surgical textbook ★ Thoroughly revised and completely up-to-date ★ The section on cardiac surgery has been rewritten and to reflect its increasing importance there is a completely new section on trauma surgery ★ Over 100 new illustrations ★ Comprehensively indexed ★ Many references for further reading

Reviews

'What differentiates this textbook of surgery from many others is the clarity and simplicity of the text, the very liberal use of complementary tables, the illuminating simple diagrams, and the book's clinical relevance. The ease with which it may be read and the subject material understood makes this book a superior choice for students and residents interested in learning the essentials of surgical practice' *The New England Journal of Medicine*

'This book is highly readable and is a real contribution to surgical education.' *Archives of Surgery*

'It should be a great success on both sides of the Atlantic.' *Annals of the Royal College of Surgeons*

'... Covers very well an extensive range of material which is well illustrated and readily comprehensive. It should be very useful equipment for the trainee surgeon for the Australasian college.' *New Zealand Medical Journal*

NEW FROM BUTTERWORTHS

MANAGEMENT OF ABDOMINAL HERNIAS

H Brendan Devlin MA MD MCh (Dublin) FRCS(England) FRCS(Ireland) FACS
Consultant Surgeon, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

- ★ **the author is a leading authority on hernia management**
- ★ **extensively illustrated with high quality line drawings, half-tones and colour photographs.**

Management of Abdominal Hernias is the most comprehensive work to date on the subject. In this exhaustive volume the author discusses the historical background to hernia management and its influence on current practice.

The basic sciences and operative technique of hernia surgery are dealt with in practical terms and guidance on complications and postoperative care is supported by new data based on long term studies.

"This book is beautifully produced, clearly written and profusely illustrated, mainly by excellent line drawings. It would be of considerable value to the surgeon in training (who, in this country, is called upon to do the majority of this type of surgery) but it would also be read with interest by his Chief."

British Journal of Clinical Practice

"The anatomy of the abdominal wall is excellently set out and clearly described and I would recommend all surgeons in training, particularly at senior house officer level, to read it.

"This is a very readable and enjoyable book. It is not directed at any particular grade of surgeon but will inform and enlighten the majority of those who read it."

British Journal of Hospital Medicine

Concise contents: Preface · General introduction and history of hernia surgery · Essential anatomy of the abdominal wall · Epidemiology and aetiology of primary hernias in adults · Logistics and economics of hernia repair · Principles in hernia surgery · Anaesthesia · Complications of hernia in general · Groin hernias in babies and children · Umbilical hernia: operation in babies and children · Diagnosis of a lump in the groin in the adult · Inguinal hernia in adults · Femoral hernia · Extraperitoneal or preperitoneal repair of groin hernias using prosthetic reinforcement · Umbilical hernia in adults · Epigastric hernia · Obturator hernia, lumbar hernia, sciatic hernia, supravesical hernia · Spigelian hernia · Incisional hernia (excluding parastomal hernia) · Parastomal hernia · Complications of hernia repair · Epilogue and general conclusions · Biographical notes · References and further reading · Index

Mr T N Walsh, Professorial Surgical Unit, St James', Dublin 8, Ireland

Dispersed islet autotransplants (fresh and cryopreserved) can produce normal fasting insulin and glucose concentrations. Following an intravenous glucose challenge, however, the insulin response is impaired and glucose clearance delayed. This study examines the diurnal insulin and glucose response to feeding in recipients of fresh islet autografts ($n=6$), *recipients of cryopreserved islet autografts* ($n=3$), *normal unoperated controls* ($n=10$) *and insulin treated pancreatectomized diabetic dogs* ($n=7$). *Mean fasting insulin and glucose levels were similar in all groups. After feeding, insulin profiles in both transplant groups were near normal while significant hyperinsulinaemia occurred in insulin treated diabetic dogs. Mild postprandial carbohydrate intolerance was observed in transplant recipients but glycosylated haemoglobin levels were similar (mean(s.d.)) to normals (6·88(0·86) per cent, 6·86(0·5) per cent respectively). Dispersed islet autotransplantation with portal insulin delivery produces near normal insulin and glucose profiles suggesting that this may represent a suitable treatment for insulin dependent diabetes.*

Keywords: Pancreatic islet transplantation, cryopreservation, insulin profiles, glucose profiles

The discovery of the link between the pancreas and diabetes by Minkowsky and von Mering in 1889[1] led to an interest in pancreatic transplantation as a treatment for the disease. In 1893 Williams in Bristol transplanted fragments of a sheep's pancreas into a diabetic boy. Although he could not convincingly demonstrate function, he expressed optimism in the principle[2]. With the discovery and availability of injectable insulin it was hoped that metabolic abnormalities would be corrected and a normal life ensue. While death from ketoacidosis was avoided it soon became apparent that secondary changes occurred in the tissues of diabetics which led to increased morbidity and mortality compared with the normal population[3].

The aetiology of diabetic complications remains unclear but is likely to be related to persistent metabolic abnormalities[4]. All forms of current therapy administer insulin peripherally and are associated with elevated insulin levels. Certain diabetic complications have been attributed to hyperinsulinaemia[5] and deterioration of intermediary metabolism has been associated with intensified insulin therapy[6].

Dispersed intrasplenic islet transplantation is intended to correct intermediary metabolism by supplying insulin and counter-regulatory hormones in a physiological manner. These grafts possess a number of practical advantages over pancreatic segments. For instance, they can be stored indefinitely by cryopreservation and can be safely injected into a portally draining site for optimum insulin delivery. Both fresh[7] and cryopreserved[8] grafts have been shown to correct levels of insulin, glucose and intermediary metabolites in the fasting animal. Following an intravenous glucose challenge, however, the insulin response is impaired and glucose clearance delayed. The significance of this for response to normal daily challenges of food and exercise is unknown.

The purpose of this study, therefore, was to examine diurnal glucose and insulin profiles in dogs with islet autotransplants (fresh or cryopreserved) and to compare them with two other groups; normal dogs and pancreatectomized diabetic dogs treated with twice daily insulin injections.

Materials and methods

Twenty-six male and female mongrel dogs weighing between 12 and 24 kg were used in the study. The experimental groups were:

Group 1

Ten unoperated dogs acted as normal controls.

Group 2

Seven animals underwent total pancreatectomy and received twice daily insulin injections. Frequent determinations of blood glucose were made each day before the study to establish the dose of insulin that was sufficient to maintain a fasting blood glucose of less than 12 mmol/l. The study was performed 10–14 days after pancreatectomy to avoid problems with the interpretation of insulin results as a consequence of insulin antibody formation.

Group 3

Six animals received a dispersed pancreatic autotransplant as described previously[7] and were studied at 10–12 weeks after transplantation.

Group 4

Three animals received a dispersed pancreatic graft prepared as for group 3 but cryopreserved as previously described[9] and stored in liquid nitrogen at −196°C for 2 weeks. These animals were studied at 10–12 weeks after transplantation. Four other recipients of cryopreserved grafts suffered graft failure before 10 weeks and were not considered in this study.

Each study was performed following an overnight fast. On the morning of the study a heparinized 21G (0·80 × 40 mm) cannula was inserted into a foreleg vein at 05.30 hours. Blood samples for glucose and insulin determinations were taken at intervals of 2 h from 06 00 to 22.00 hours. Animals were fed a standard meal at 10.00 hours and again at 16 00 hours. Further blood samples were taken at intervals of 5, 10, 15, 20, 30, 45, 60 and 90 min after each meal. This protocol was modified in the insulin treated group where subcutaneous insulin was administered at 10.00 hours and 16 00 hours with feeds. In addition to the 2-hourly samples blood was taken 30 and 60 min after meals. All samples were stored on ice and plasma glucose was assayed on the day of the experiment. The plasma for insulin determination was

separated and stored at $-20°C$ for batch assay at a later date by methods described previously[7]. Glycosylated haemoglobin levels were assayed in normal dogs and in the recipients of fresh islet grafts at intervals of 1 month. The monthly results were pooled and compared with the normal range.

Test meal

The morning meal consisted of 750 g proprietary dog food (Chum, Pedigree Foods Ltd., Melton Mowbray, UK) and 150 g of food mixer (Chum Mixer, Pedigree Foods Ltd.). The afternoon meal consisted of 375 g dog food and 75 g mixer. Pancreatectomized dogs received pancreatic exocrine replacement therapy (Pancrex V® powder, Paines and Byrne, Greenford, UK). These quantities of food maintained weight in pancreatomized dogs

Statistical analysis

Comparison of values within groups at different times was performed using Wilcoxon's signed rank test for paired data. When comparing different groups Wilcoxon's rank sum test for unpaired data was used. When comparing fasting values within or between groups the 10.00 hours determinations were used and when comparing fasting with fed values the peak postprandial values were used. Groups were also compared at each time point during the study using Wilcoxon's rank sum test.

Results

Group 1 (Controls)

Glucose profiles. Control animals had glucose profiles which varied little throughout the day (*Figure 1*). Lowest mean values were observed at 10.00 hours. Both meals were followed by a significant rise in plasma glucose levels ($P<0{\cdot}05$) with the greater increase following the afternoon meal. The most striking feature was the narrow range of glucose concentrations during the 16 h study period, plasma glucose never exceeding 6 mmol/l.

Insulin profiles. Mean peripheral insulin concentrations showed a trough at 10.00 hours (17·1 milliunits per litre)

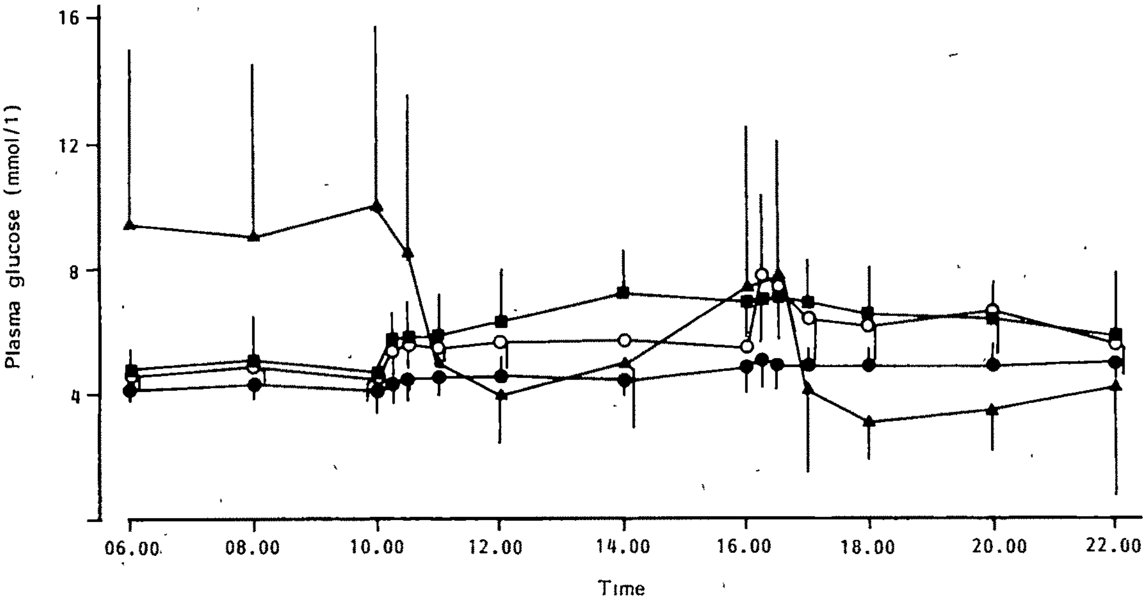

Figure 1 *Diurnal plasma glucose profiles* ●, *normal dogs* (n = *10*), ■, *recipients of fresh islet autografts* (n = *6*), ○, *recipients of cryopreserved islet autografts* (n = *3*); ▲, *insulin treated pancreatectomized diabetic dogs* (n = *7*). *Meals (and insulin injections in diabetic dogs) were supplied at 10.00 hours and 16.00 hours*

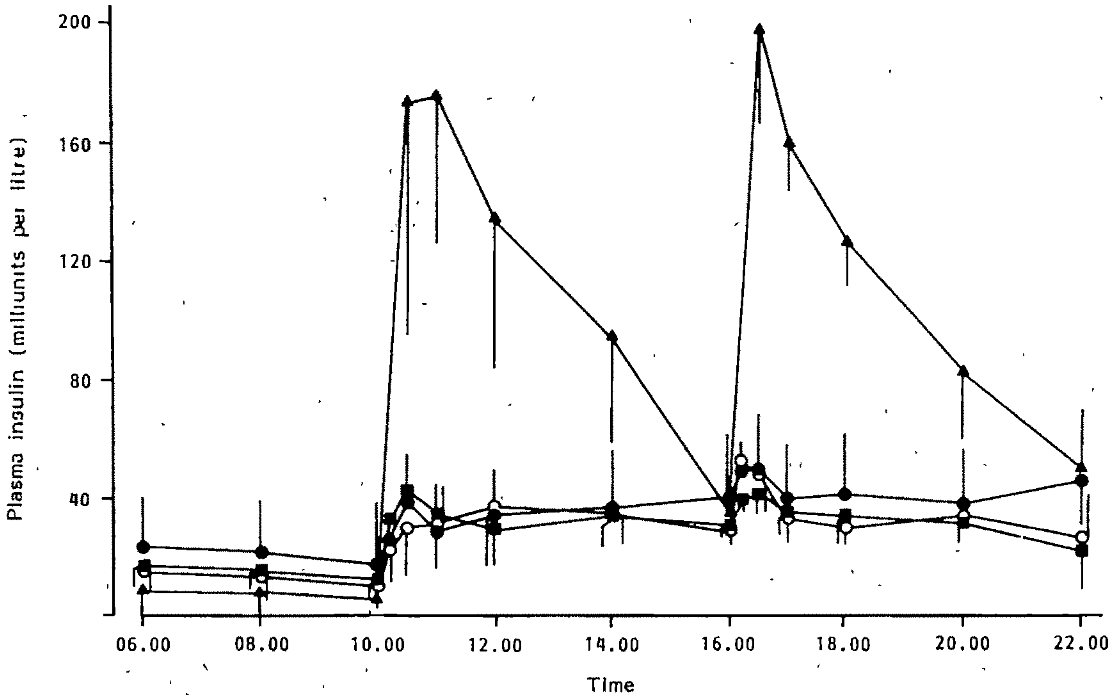

Figure 2 *Diurnal plasma insulin profiles. Key as in* Figure 1

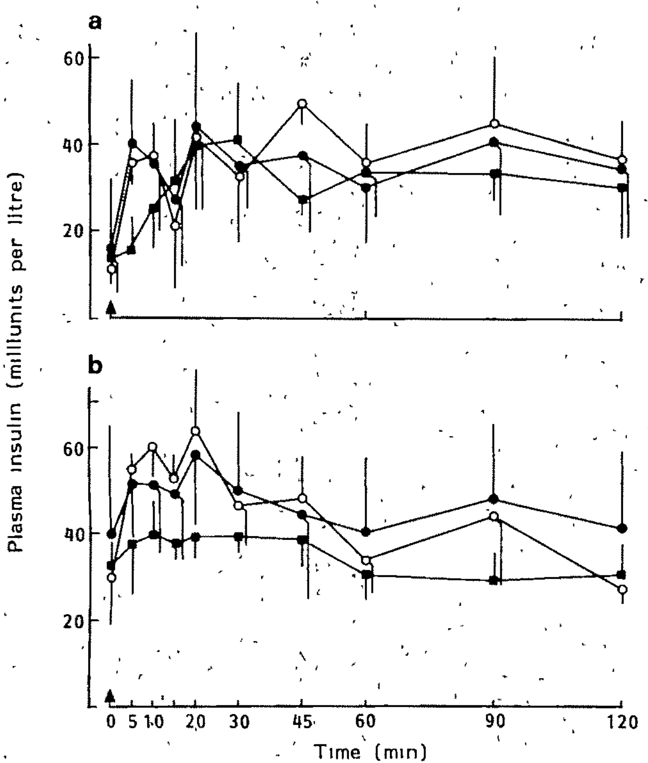

Figure 3 *Insulin response to morning meal (a) and afternoon meal (b) Key as in* Figure 1 *but with the insulin treated group omitted for clarity Arrowheads show feeding time*

(*Figure 2*). The insulin response to the morning meal was biphasic (*Figure 3*). The first peak was seen at 5 min (41·3 milliunits per litre) with a further peak of 44·6 milliunits per litre at 20 min. The response to the afternoon meal was also biphasic rising to 52·2 milliunits per litre at 5 min with a second peak of 58·4 milliunits per litre at 20 min (*Figure 3*).

Group 2 (Insulin treated diabetics)

Glucose profiles. Mean fasting glucose levels were similar to those of group 1 but the range of values was greater (*Figure 1*). Glucose concentrations fell after feeding but only the afternoon reduction was significantly different from normal, between 17.00 hours and 22 00 hours ($P<0{\cdot}05$). The animals in this group were closely observed and no hypoglycaemic signs were detected.

Insulin profiles. Mean fasting insulin concentrations were similar to those in normal animals but with a wider range of values (*Figure 2*). Following meals the mean insulin concentrations peaked at 30 min at levels of 175 milliunits per litre and 200 milliunits per litre respectively, significantly higher than controls and transplanted groups ($P<0{\cdot}01$), returning towards basal levels over the next 6 h (*Figure 2*).

Group 3 (Fresh islet graft recipients)

Glucose profiles The mean fasting plasma glucose concentrations were not significantly different from normal controls (*Figure 1*). Mild postprandial carbohydrate intolerance was observed, especially after the afternoon meal. Levels were significantly elevated compared with normals from 10.15 hours onwards ($P<0{\cdot}01$) returning to normal at 22.00 hours (*Figure 1*). In no animal did the blood glucose exceed 9·5 mmol/l at any time.

Insulin profiles. The mean fasting peripheral insulin concentrations were not significantly different from normal controls and the overall diurnal pattern was similar (*Figure 2*) but the biphasic response to meals was lost (*Figure 3*). The insulin response to the morning meal was slow to peak; the values at 5 min were significantly reduced compared with normals ($P<0{\cdot}05$). The response to the afternoon meal was blunted, though this difference only reached significance at 20 min ($P\leq0{\cdot}05$).

Glucose 4 (Cryopreserved islet graft recipients)

Glucose profiles. The cryopreserved transplant recipients had glucose profiles similar to group 3 with normal fasting glucose levels and mild postprandial carbohydrate intolerance (*Figure 1*).

Insulin profiles. The mean insulin profiles were similar to those seen in group 1 and, in particular, the biphasic response to meals was preserved (*Figures 2* and *3*).

Glycosylated haemoglobin levels

In recipients of fresh grafts glycosylated haemoglobin levels (6·88 (0·86 per cent)) were similar to those of normal controls (6·86 (0·5 per cent)) throughout the study period.

Discussion

The aims of pancreatic transplantation are to restore insulin independence and to prevent the secondary complications of diabetes. There is no convincing evidence that established diabetic complications can be reversed[10–12].

Some success has been achieved using vascularized pancreatic segment transplantation and many patients have become insulin independent. Its use remains restricted to patients in end-stage disease or to diabetic recipients of a renal transplant in whom an added burden of immunosuppression does not require justification. The morbidity and mortality rates of the technique, however, suggest that it is unsuitable for patients with early disease, the very patients in whom complications might be preventable[13].

Dispersed islet grafts, on the other hand, can be placed into a site with portal venous drainage and do not have the risks of pancreatic fistula or vascular thrombosis. It is important to establish that such grafts provide near normal diurnal insulin delivery in response to daily dietary challenges and might thereby prevent the development of secondary complications

Our study has demonstrated that the insulin response from a dispersed fresh or cryopreserved islet graft to a mixed meal was similar to that seen in normal animals. This is different from previous studies which employed intravenous glucose tolerance tests to assess graft function and demonstrated poor insulin response despite normal fasting insulin and glucose levels[7,14,15]. These studies called into question the ability of islet grafts to restore normal metabolism.

The difference between the present and previous studies may be attributed to the route of nutrient delivery. The secretion of insulin occurs at a rate determined by blood glucose and modulated by neural and endocrine influences. Oral ingestion of carbohydrate[16] and amino acids[17] is more effective than parenteral administration of the same quantity and the term 'entero-insular axis' has been coined to embrace those gut factors which contribute to the enhanced insulin response to ingested nutrients[18]. Insulin release following food is biphasic with an initial peak after 2 min followed by a more prolonged plateau response starting 5–10 min after the meal. The initial response is thought to be neurogenic owing to the release of acetylcholine and possibly other peptides from nerve endings terminating on the islet cell wall[19] When islets are denervated, as in islet grafts, the initial response is lost which is consistent with the absent first phase insulin response to the morning meal in the present study. Certain gastrointestinal hormones, however, that are potent stimulators of insulin secretion (e.g gastroinhibitory polypeptide[20]), are released in response to vagal activity and intraluminal nutrients. This probably accounts for the near normal diurnal profile in this study.

The intravenous glucose tolerance test has been used to assess islet graft function in most other studies of pancreatic islet transplantation. Nevertheless, it may not be suitable for studying the dispersed, denervated, heterotopically located islet graft as it disregards the response of the entero-insular axis and probably underestimates the true functional reserves of the graft

Neither group of transplanted animals exhibited hyperinsulinaemia when compared with the insulin treated group in which plasma insulin concentrations four times those of normal controls were required to achieve postprandial euglycaemia. This is consistent with the findings of Tchobroutsky where four- to fivefold increases in insulin concentrations were required to achieve euglycaemia in insulin treated diabetics[21]. Insulin is normally delivered into the portal vein and a significant proportion is extracted by the liver, which results in a difference (of between two and ten times) in insulin concentration between portal and peripheral blood[22]. Current insulin therapy, continuous subcutaneous insulin infusion and segmental transplantation all result in hyperinsulinaemia because of peripheral insulin delivery, and persistent hyperinsulinaemia has been implicated in the pathogenesis of certain diabetic complications[5].

Mild postprandial carbohydrate intolerance was demonstrated in animals with both fresh and cryopreserved grafts. Islet denervation resulting in the loss of the initial insulin response may have contributed to the mild intolerance following the morning meal. A suboptimal islet mass may account for the blunted insulin response to the afternoon meal in group 3 animals. While as little as 13 per cent of the intact pancreas will maintain normal fasting blood glucose levels, glucose tolerance is impaired when more than 50 per cent of the intact canine pancreas is removed[23] Our dispersed islet implant mass was difficult to quantify and was unknown in these transplants but Kretschmer *et al*., using a similar method of graft preparation, estimated the islet yield as 7·4 per cent[24]. However, their grafts were associated with low fasting insulin levels and an insignificant response to a glucose challenge which suggests that the yield in the current study was considerably greater.

It is unclear whether mild carbohydrate intolerance with near normal insulin levels would be significant in terms of diabetic complications. Glycosylated haemoglobin levels in transplanted animals remained within the normal range throughout the period of study and at 27 months after transplantation no evidence of diabetic retinopathy has been detected[25].

Cryopreserved graft recipients had a normal diurnal insulin response to meals confirming that ultralow temperature storage did not result in permanent injury to insulin production or release mechanisms[26]. In another study the insulin response to an intravenous glucose tolerance test in a group of recipients with cryopreserved grafts was greater than that of fresh graft recipients[8] and Warnock *et al.* found that the duration of hyperglycaemia following an oral carbohydrate load was shorter in recipients with cryopreserved grafts[27]. He attributed this to the 'purifying effects' of cryopreservation on the potentially harmful exocrine contaminants.

Dispersed islet grafts transplanted to a portally draining site restore near normal diurnal insulin and glucose profiles. Function is maintained following cryopreservation If the problems of islet harvesting and rejection can be overcome these grafts might prevent the secondary complications of diabetes when transplanted to newly diagnosed insulin dependent diabetics.

A questionnaire designed to investigate the technical training of general surgical trainees was distributed throughout Scotland. A total of 222 questionnaires were sent out and 179 (81 per cent) were returned. Of the responders, 38 per cent felt that the overall operative workload was too small and the majority thought that there was too little emphasis on supervised operating. Two-thirds of trainees were generally satisfied with the amount of unsupervised operating, although a substantial proportion (21 per cent) sometimes felt out of their depth when performing delegated emergency operations. Few had attended craft workshops or travelled to other centres, but of those who had, most considered both activities to be very useful. Photographic atlases and videos were not generally felt to be of great value by those who had used them. The majority of trainees did not believe that research activity had interfered excessively with their technical training.

Keywords: Technical training, general surgery

Despite the obvious importance of technical training in surgery, there has been little attempt to study the way in which operative skills are taught in this country. Furthermore, although there is a resurgence of interest in training[1–6] it is clear that not all surgeons are entirely happy with current methods[7,8]

Before devising ways of improving the present system of teaching practical surgery, it is important to identify possible areas of weakness In an attempt to do this, a survey of junior surgeons throughout Scotland has been carried out to assess their attitudes towards training.

Method

The questionnaire did not include personal details other than training grade, thus preserving the anonymity of both responder and centre It was mailed to 222 general surgical trainees who were identified by personal contact with 25 Divisions of Surgery in teaching and district general hospitals A specimen questionnaire was sent to each institution, and in no instance was permission to circulate it refused. We believe that almost all general surgical trainees in Scotland were contacted by this means

The questionnaire was divided into four main sections

Section I was designed to investigate operating workload by ascertaining the number of half-day sessions spent in the operating theatre per week, each trainee was also asked whether the amount of time spent in theatre assisting, being assisted by a senior member of staff or operating alone was satisfactory.

Section II asked the trainees whether delegation of cases was appropriate, and in particular whether they ever felt out of depth when operating alone.

Section III explored the perceived role of photographic atlases, videos, surgical workshops and travel to other centres to watch recognized experts operate

Section IV posed the question. 'Do you feel that the need for doing research and writing scientific papers has diverted your attention excessively from training in the technical aspects of surgical practice?'

Results

Of the 222 questionnaires sent out, 179 (81 per cent) were returned. It was impossible to evaluate eight because the trainee was in a post which did not involve operative surgery; this left 171 (77 per cent) replies available for analysis. Twenty-five came from senior registrars and 146 from registrars or senior house officers, 64 were returned from district general hospitals and 107 from teaching hospitals. Only two of the senior registrars were at district general hospitals at the time of circulation.

The number of half-day sessions spent by trainees in the operating theatre each week is shown in *Figure 1* This varied from no regular sessions to seven, but the majority of trainees worked three or four. When asked to give a subjective opinion on workload, most felt that it was satisfactory, although a sizeable proportion thought that there was too little, and only one considered that there was too much (*Table 1*). The proportion of trainees who were dissatisfied with the operative workload was smaller in the district general hospitals than in teaching hospitals.

Operating theatre experience was subdivided into three categories: assisting, supervised operating and operating alone. The trainee surgeons were asked if they were exposed to the right amount, too little or too much of each of these categories. Very few thought that they did too little assisting, but the majority felt they had too little supervised operating and a large minority considered that there was too little operating alone. On the other hand, assisting was the only one of the three areas in which a significant number of trainees thought there was too much (*Figure 2*).

Trainees' attitudes to the degree of difficulty of operations they were expected to perform unsupervised were then investigated The replies (*Tables 2* and *3*) indicated that most

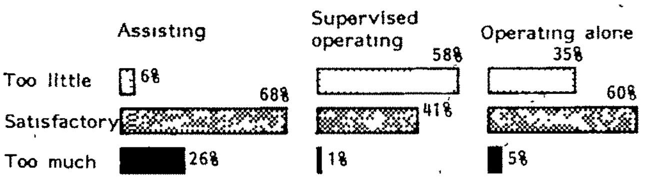

Figure 2 *Summary of trainees' attitudes to the three components of operating theatre experience*

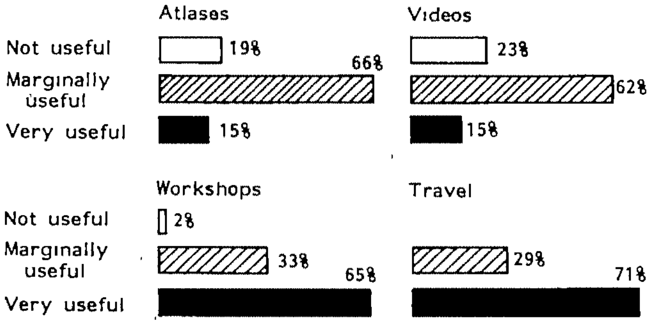

Figure 3 *Trainees' attitudes towards four adjuncts to technical surgical training: atlases (used by 107 trainees, 63 per cent), videos (used by 53, 31 per cent); workshops (used by 48, 28 per cent), and travel (used by 34, 20 per cent)*

thought such operations were at the right level of difficulty, but it is worrying to note that although only 9 per cent sometimes felt out of their depth while performing elective operations, this figure rose to 22 per cent for emergency procedures. Another important finding was that the percentage of trainees who were sometimes operating beyond their capabilities in emergency procedures was significantly greater in district general hospitals (32 per cent) than in teaching hospitals (15 per cent).

Four other aspects of surgical training were also examined (*Figure 3*). Photographic atlases had been used by many, but most had found them only marginally useful. Similarly, although videos had been used by a smaller proportion, they were not often considered to be very useful. Conversely, both workshops and educational travel were rated highly, but relatively few had experienced either.

Finally, the majority of responders did not feel that research had interfered excessively with their technical training (*Table 4*). However, in the interests of simplicity, no queries regarding the amount of research were included, and it is possible that a considerable number of the registrars and senior house officers had no research experience.

Discussion

Little is known of surgical trainees' attitudes to their own training, but in a recent small study from the Mersey region, only nine out of 16 postfellowship registrars considered their training to be good[9]. Although the median number of major operations performed or assisted at over a 3-month period was 30, the median number of supervised operations was only three. In a larger questionnaire study from America, Ritchie and Cohn questioned 922 final-year residents and found that over 80 per cent of the respondents acted as the operating surgeon in more than two-thirds of cases, supervision being provided in roughly 50 per cent of these[10]. It is impossible to make a direct comparison between these two studies, but it does seem that in the USA supervised operating is more common than in the UK, even among senior trainees From our study, it is evident that general surgical trainees in Scotland feel that too little emphasis is placed on supervised operating, and that some juniors are unhappy about being left alone, especially in emergency situations.

Good surgical technique is of vital importance and trainees should not have to acquire it at the expense of their patients. However, there is evidence that junior surgeons do sometimes operate beyond their capabilities, with detrimental effects. For example, the majority of benign bile duct strictures are caused by inexperienced surgeons performing cholecystectomies without senior assistance[11,12], and the recent Confidential Enquiry into Perioperative Deaths has highlighted inadequate consultant supervision as one of the major factors contributing to avoidable mortality[13]. The marked variability in the results of surgical operations across the country is a related phenomenon[14–17], which may be partly ascribed to lack of uniformity of technical expertise. It has been shown that technical factors probably constitute the main determinant in the development of postoperative complications[18].

Clearly, then, more emphasis should be placed on technical training, and the answers to the questionnaire described in this article suggest some areas where improvements could be made. Adequate supervision in the operating theatre should be available, not only for the safety of patients but also for the benefit of trainees. However, if more operating is to be done by surgical trainees assisted by senior surgeons, it is inevitable that the procedures will take longer. Allowance must be made for teaching in the assessment of theatre usage, waiting lists and consultant staffing levels.

In view of the favourable reaction to workshops, a more structured approach to the initial teaching of surgical skills should perhaps be adopted, with the wider use of simulated procedures. There is some evidence that such an approach can pay dividends at an early stage of training[5,19]. The workshop may also be suitable for teaching more senior trainees the rudiments of complex modern techniques. Travel to centres of surgical excellence is also considered to be useful, and appropriate opportunities could be built into training schemes. Most could probably be gained from such visits at a fairly advanced stage of training, when nuances of technique would be more easily appreciated.

In recent years, technical training has perhaps received less attention than it deserves. Now may be time to redress the balance We believe that this survey highlights some deficiencies and may be of value in the structuring of future training programmes

The effect of long acting somatostatin analogue, SMS 201-995, on postprandial dumping syndrome was studied in eight patients with Billroth II gastric resection. Each patient was subjected to two oral glucose challenges with 75 g glucose. One challenge was premedicated with 50 µg SMS 201-995 subcutaneously 15 min before the oral intake of glucose, the other with placebo. With placebo all patients experienced the subjective symptoms of the early dumping syndrome with significant ($P<0.001$*) increases (mean (s.d.)) in pulse rate (from 66 (8) to 102 (10) beats/min), in packed cell volume (from 0·36 (0·05) to 0·43 (0·1) l/l) and in the plasma levels of vasoactive intestinal polypeptide (from 3·0 (0·5) to 10·2 (1·8) pmol/l). During the somatostatin study the subjective symptoms and the changes in the various parameters were not detected. In the control study seven patients showed postprandial hypoglycemia. In these patients significant elevations (*$P<0.001$*) in the insulin level (from 10 (0·9) to 40 (9·1) µE/ml) and gastric inhibitory peptide (GIP) concentration (from 100 (13) to 220 (41) ng/l) were seen, compared with the initial values. During the application of SMS 201-995 hypoglycaemia did not develop and plasma insulin and GIP concentrations remained unchanged. These results indicate that the long acting somatostatin analogue alleviates the symptoms of early and late postprandial dumping syndromes.*

Keywords: Dumping syndrome, long acting somatostatin analogue, gastrointestinal hormones

Dumping syndrome can be a serious complication after gastric surgery. Investigations have shown that the release of gastrointestinal hormones plays an important role in the appearance of symptoms[1,2,3]. Other investigations have demonstrated that native cyclic somatostatin has a beneficial effect on symptoms associated with the dumping syndrome[4,5]. The benefit of somatostatin is based theoretically on its ability to block hormone release. Recently a new long acting somatostatin analogue was developed[6]; with its long action and simple subcutaneous administration it has some advantages compared with native somatostatin. The effect of long acting somatostatin analogue on the symptoms characteristic of the dumping syndrome has been investigated

Patients and methods

Eight male patients who had developed symptoms of early and late dumping syndromes following Billroth II gastric resection were investigated during this trial (mean age, 51 years). Each patient underwent two oral glucose challenges with 75 g glucose in a standard 150 ml dose of 50 per cent glucose. One of the challenges was premedicated with 50 µg SMS 201-995 (Sandostatin®, Sandoz, Basel) subcutaneously 15 min before the oral intake of glucose; the other challenge was premedicated with placebo (isotonic sodium chloride). The premedications were assigned in double blind fashion and random order. The patients gave informed consent.

The subjective symptoms of the patients (palpitation, dizziness, fainting, vomiting and abdominal distension), as well as the pulse rate and the blood pressure were monitored at 5 min intervals during the trial. Blood was withdrawn without venous occlusion for determination of packed cell volume, glucose, insulin, gastric inhibitory polypeptide (GIP) and vasoactive intestinal polypeptide (VIP) levels determined by standard techniques and radioimmunoassays (Immuno Biological Laboratories GmbH, Hamburg, FRG).

Blood samples were taken 15 min before the glucose administration, at zero time and every 30 min during the total 240 min following the challenge The results of the two glucose challenges were compared using Student's paired *t* test.

Results

The baseline parameters of patients in the two studies did not show any statistical differences. The levels of the investigated hormones were normally distributed in this study and the standard deviations were relatively low.

In the placebo study all patients experienced the typical subjective symptoms (palpitation, fainting, weakness, epigastric distress) of the early dumping syndrome. During the glucose challenges with SMS 201-995 premedication three patients experienced nausea following the oral intake of glucose, but the characteristic signs of early dumping were absent. In the placebo study significant increases were detected (initial levels and maximum changes; mean (s.d.)) in the pulse rate (from 66 (8) to 102 (10) beats/min) in the packed cell volume (from 0·36 (0·05) to 0·43 (0·1) l/l) and in the plasma levels of VIP (from 3·0 (0·5) to 10 2 (1·8) pmol/l). During the somatostatin study there were no changes detected in these parameters. On the other hand there was a statistically significant difference in the changes of these parameters between the two glucose challenges ($P<0.001$, *Figure 1*). Blood glucose levels increased rapidly and reached their maximum value 30 min after the oral intake of glucose in the placebo study, while in the somatostatin analogue study the maximum was reached at 90 min. Hypoglycaemia developed in seven patients in the placebo study. During this period the blood glucose decreased from an initial level (mean (s.d.)) of 3·8 (0·8) to 1·8 (1·1) mmol/l. During the SMS 201-995 application no hypoglycaemia was detected. In the placebo study the insulin (from 10 (0·9) to 40 (9·1) µE/ml) and GIP levels (from 100 (13) to 220 (41) ng/l) showed a significant ($P<0.001$) elevation compared with the initial values, while in the somatostatin study the plasma insulin and GIP remained unchanged (*Figure 1*).

Discussion

The dumping syndrome following gastric surgery is a consequence of compensatory mechanisms. Rapid transit of

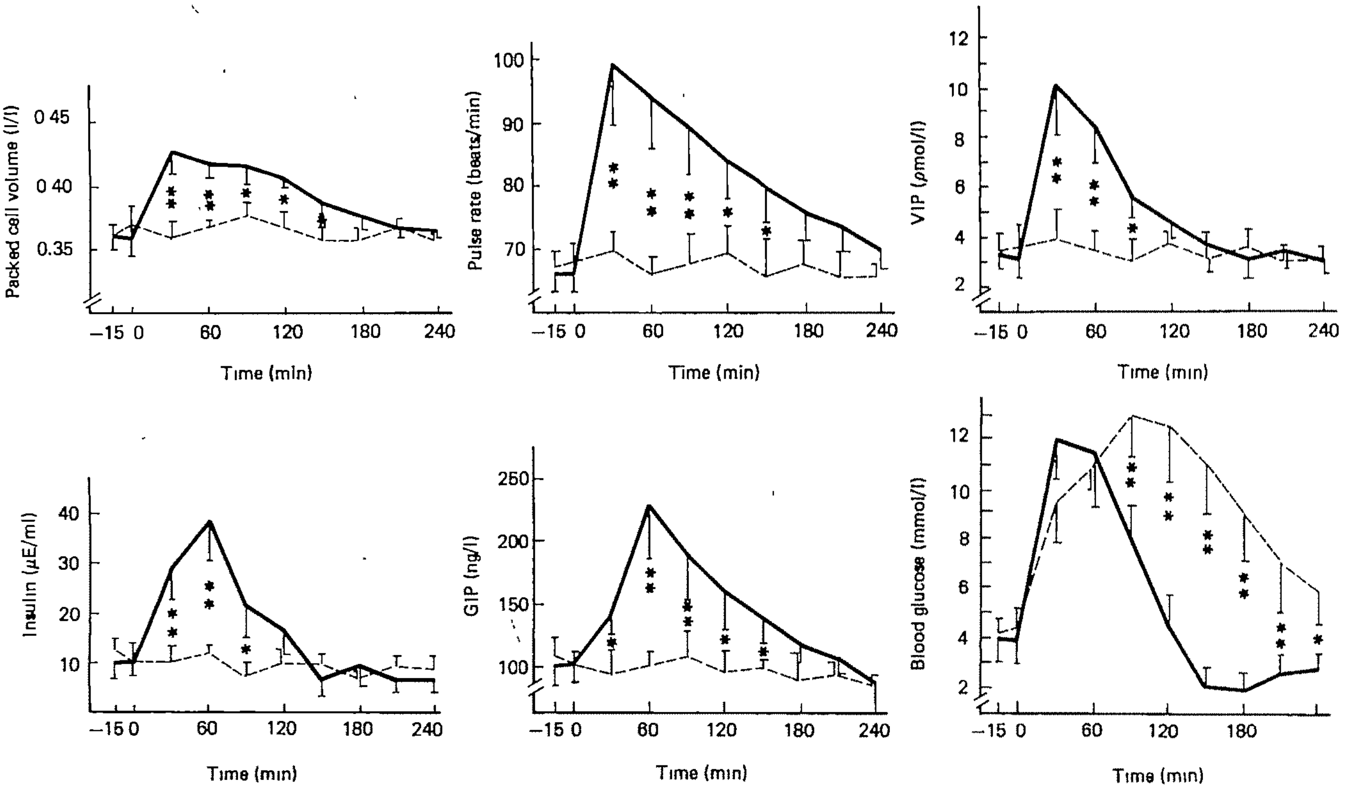

Figure 1 *Packed cell volume, pulse rate, vasoactive intestinal polypeptide (VIP), insulin, gastric inhibitory peptide (GIP) and blood glucose levels during glucose challenges with (---) and without (—) long acting somatostatin analogue SMS 201-995 (**$P<0.001$, *$P<0.01$)*

hyperosmolar food into the intestine causes a release of fluid and electrolytes into the upper small bowel. Simultaneously, haemoconcentration and the typical subjective symptoms of early dumping syndrome develop. During this process hormonal changes can also be observed; however, their primary role has not yet been established[1,2,3]. The elevation of VIP seems to be an important factor, because the infusion of VIP produces symptoms equivalent to the early dumping syndrome[2]. The main clinical feature of the late dumping syndrome is the reactive postprandial hypoglycaemia. It appears that the increased insulin release may in part be because of the relative hyperglycaemia and partly because of the increase in the GIP level.

The symptoms of the postprandial dumping syndrome seem to develop as a result of the release of various peptides. Somatostatin is a tetradecapeptide which inhibits the release of numerous gastrointestinal and pancreatic hormones, as well as inhibiting the secretion of fluid and electrolytes in the small intestine and increasing the gastrointestinal transit time[7]. These effects suggest that somatostatin might be beneficial in alleviating the signs of dumping syndrome. Previous studies are controversial[4,5,8].

Native cyclic somatostatin has a short half-life and therefore its clinical use is limited. Like native somatostatin SMS 201-995 suppresses the secretion of several regulatory peptides[7]; its effect is long acting. A previous study by Hopman *et al.* demonstrated that SMS 201-995 is effective in the prevention of clinical symptoms related to the dumping syndrome[9]. Hopman *et al.* studied only the changes in plasma insulin level and his results did not explain all the signs characteristic of this syndrome. In our study the hormonal changes provide a more detailed explanation of the beneficial effect of SMS 201-995 on the symptoms of the dumping syndrome. Our results demonstrate that the long acting somatostatin analogue alleviates not only the clinical signs of early dumping syndrome, but also inhibits the release of VIP This compound also blocks the increases in insulin and GIP which play a role in the development of postprandial hypoglycemia. Our study has shown that the long-acting somatostatin analogue SMS 201-995 has a beneficial effect in the prevention of both the subjective symptoms and the hormonal changes related to the early and late dumping syndrome following gastric surgery Therefore this compound might be of value in the management of the circulatory and metabolic disturbances associated with this syndrome.

Biliary leakage and peritonitis following removal of T tubes after bile duct exploration

P. G. Horgan, A. C. Campbell*, G. R. Gray and G. Gillespie

Department of Surgery, Victoria Infirmary, Glasgow G42 9TY, UK
Correspondence to: Mr P. G. Horgan

After bile duct exploration for stones, it is common practice for surgeons to place a rubber T tube into the bile duct for a period usually of not less than 7 days. Farquharson recommends that 7–10 days should elapse before the tube is withdrawn[1]. The advantages claimed from this practice are firstly that it allows safe egress of bile in the event of a residual undetected bile duct stone obstruction and, secondly, that it enables postoperative T tube cholangiography to confirm clear ducts before T tube removal. The T tube forms a fistulous tract between the common bile duct and the skin, and when allowed to mature for 6 weeks even allows manipulation of a Burhenne catheter into the bile duct after removal of the tube. However, problems with T tubes can and do occasionally occur, and in a recent large review of surgical bile duct stones a 2·2 per cent complication rate was directly attributed to T tube drainage[2].

Safe removal of T tubes depends on the irritant properties of the T tube stimulating a reactive granulation track around the tube, thereby ensuring a temporary biliary cutaneous fistula which will normally close within a few days of T tube removal. It is noteworthy that 25 years ago the problem of bile duct leakage into the peritoneal cavity was reported following the introduction of a non-irritant, non-allergenic T tube made of polyvinyl chloride[3]. Winston *et al.* reported on four cases of biliary peritonitis with the use of polyvinyl chloride T tubes but cited references to 2000 explorations using latex rubber T tubes without this complication. The subsequent introduction of latex-based materials for T tube manufacture resolved this problem, and such material remains the most common composition for T tubes in use today. We report here, however, a disturbing series of 15 cases where the removal of a particular variety of T tube was followed by significant biliary leakage and peritonitis which required active intervention in 11 of 15 cases.

Case reports

Fifteen patients from five separate Scottish hospitals underwent elective cholecystectomy and exploration of the bile duct for stones (Victoria Infirmary, Glasgow: five cases, Ross Hall Hospital, Glasgow: two cases; Western Infirmary, Glasgow: five cases, Royal Alexandra Hospital, Paisley: one case; Ninewells Hospital, Dundee: two cases).

There were nine men and six women, and ages ranged from 22 to 70 years. In 14 cases a soft latex rubber T tube (Warne Franklin Surgical Products Ltd, High Wycombe, UK) was placed into the bile duct. In one patient there is doubt about which of two available varieties of T tube was used, but the possibility that a Warne T tube had been used could not be excluded. In every case, a postoperative T tube cholangiogram had confirmed that the bile duct was free from residual stones or other obstruction. Most of the T tubes were removed between 10 and 13 days after surgery (ten cases). The earliest T tube removal was at 7 days after operation and two patients had T tubes *in situ* for 20 days or more.

Ten patients developed acute generalized biliary peritonitis immediately after T tube removal and required urgent active intervention (laparotomy and drainage, eight cases; percutaneous catheter drainage, two cases). One of these patients required two separate laparotomies and one required percutaneous drainage during a hospital stay of 43 days.

One patient was readmitted with biliary peritonitis 2 weeks after hospital discharge following T tube removal and required percutaneous drainage on two separate occasions for a large subhepatic bile collection.

Four patients who developed localized peritonitis immediately after T tube removal were treated conservatively with intravenous fluids and antibiotics, although one of these patients suffered septicaemia. All patients survived. The inpatient hospital stay ranged from 18 to 45 days (average 27 days).

Discussion

The unexpected cluster of cases of biliary peritonitis after T tube removal raised questions of common factors in aetiology. Seven cases encountered at the Victoria Infirmary, Glasgow and Ross Hall Hospital, Glasgow, occurred within a period of a few months and it was quickly established that the T tube used had been manufactured by Warne Franklin Surgical Products Ltd.

Preliminary enquiry revealed that in September 1986 the specification of urinary catheters and tubes had been changed. The company had developed a new non-allergenic, non-irritant latex which was used to manufacture their Foley catheters, and the process had been extended to include their T tubes. At this time the two cases reported here from Ninewells Hospital, Dundee, led to a surgical decision to remove Warne tubes from their storage shelves, since which time no further misadventures have occurred in that department. It was around this time that Warne Franklin Surgical Products Ltd. apparently stopped T tube manufacture. However, large stocks of these T tubes remained available for use, and following a cluster of cases at the Western Infirmary, Glasgow, one of the surgeons altered his practice in favour of direct bile duct closure without drainage.

That substantial stocks of Warne T tubes may remain in many hospitals seems likely, and is reflected by cases reported here from five separate hospitals.

While it is accepted that sporadic mishap may follow the use of any variety of T tube, a recent survey[4] on the use of T tubes after common bile duct exploration calculated the risk of biliary peritonitis each time a T tube is removed to be of the order of 0·84 per cent, or one in every 119 explorations. This incidence of bile leakage seems much higher than previously reported experience[3]. It is not clear in the study by Corbett *et al.*[4] which manufacturer's T tube was used. Our observations raise the question of whether a preponderance of non-allergenic T tubes in that report may account for the high incidence of bile leak. The cluster of cases reported here, where T tubes from Warne Franklin Surgical Products Ltd. were certainly used in 14 cases, suggests strongly that the original search for a non-irritant, non-allergenic tube has proved so successful that bile T tubes manufactured by the company have failed to allow mature T tube tracks to form. Nevertheless, no information on the likelihood of such mishaps has so far reached Regional Health Boards. We therefore recommend that surgeons remove Warne T tubes from their shelves.

Compartment syndrome: a cautionary tale

N. G. Stoodley and W. H. F. Thomson

Department of Surgery, Gloucestershire Royal Hospital, Great Western Road, Gloucester, GL1 3NN, UK

Correspondence to: Mr W. H. F. Thomson

Compartment syndrome is a condition in which increased tissue pressure within a closed anatomical space reduces capillary perfusion sufficiently to compromise viability of the enclosed tissues. The acute syndrome is most commonly post-traumatic, but rarely complicates operative positioning of patients. We report a case of bilateral lower limb compartment syndrome occurring after surgery with a patient in the lithotomy position in Lloyd–Davies supports.

Case report

A 26-year-old 60 kg man who had 6 months previously undergone total colectomy for fulminating ulcerative colitis was admitted for restorative proctectomy. All preoperative investigations were normal. The patient was positioned in Lloyd–Davies supports to the satisfaction of both surgeons. The procedure took 4 h with the table positioned head-down for 2 h. There were no surgical complications. The patient was hypotensive with a systolic blood pressure of 80 mmHg for the first half of the procedure.

When reviewed 4 h postoperatively the patient complained of pain in both calves. On examination both were swollen, with prominent superficial veins. He had good peripheral pulses and capillary return, and sensation was normal to light touch in both legs. There was no increase in pain on passive movement of feet or toes. Examination by Doppler ultrasonography showed good arterial and deep venous flow. Treatment was symptomatic.

The next morning his pain had lessened but signs were unchanged. By midday, he had altered skin sensation overlying the lateral compartments of both legs, and a right foot drop. A diagnosis of bilateral compartment syndrome was made and he underwent emergency bilateral four-compartment fasciotomy.

At operation, all compartments in both legs were affected with doubtful muscle viability in the right anterior and peroneal compartments, which was confirmed at a second procedure when some necrotic muscle had to be excised.

The fasciotomy wounds were allowed to heal by second intention and the patient made a good functional recovery although he had some weakness of dorsiflexion of the right ankle and altered sensation in the distribution of the right deep peroneal nerve.

Discussion

The diagnosis of compartment syndrome should not be missed or delayed. The early symptoms are due to reduced perfusion of nerve and muscle cells and classically include pain out of proportion to physical findings, a tense compartment, paraesthesiae in the distribution of nerves running through the compartment, and muscle weakness with pain on passive stretching. Peripheral pulses are unchanged until late in the process when intracompartmental pressure approaches the diastolic pressure. A diagnosis of compartment syndrome was entertained on the evening of surgery but was considered unlikely in view of the lack of neurological signs. The operative time seemed insufficiently long to support such a diagnosis.

Bilateral lower limb compartment syndromes have previously been reported in patients undergoing prolonged operation in the lithotomy position[1–3] but we are unaware of its having occurred after a 4 h procedure in this position. Patients in the lithotomy position are at risk from decreased lower limb perfusion through two mechanisms: first by compression against supports, and secondly from elevation of the limb above heart level, reducing perfusion pressures. In our patient, two other factors were probably of importance: first the initial 2 h of hypotension and, second, his having well developed muscles (he was a keen oarsman), allowing little room for expansion within compartments.

Our patient suffered unfortunate muscle loss from delay in diagnosis due to our ignorance of this hazard and our consequent disbelief in the possibility until the physical signs were advanced. Earlier diagnosis and fasciotomy would have saved him from some disability. Awareness of this possibility by surgeons operating in young fit patients in prolonged lithotomy, and early action, will prevent such catastrophic consequences.

Gastrocolic fistula as a complication of benign gastric ulcer: report of four cases and update of the literature

D. I. Soybel*,
A. Kestenberg†,
E. M. Brunt§ and
J. M. Becker*†

Departments of Surgery and Pathologly§, Washington University School of Medicine, Saint Louis, Missouri and University of Utah School of Medicine†, Salt Lake City, Utah, USA*

Professor J. M. Becker,
Department of Surgery,
Brigham and Women's Hospital,
75 Francis St, Boston, Massachusetts
02115, USA

Four cases of gastrocolic fistula complicating benign gastric ulcer are described, bringing the total number of individually reviewed cases in the English language literature to 108. A review of 30 cases reported in the past 10 years reveals a surprisingly high percentage of young, female patients. Three-quarters of these patients used steroidal or nonsteroidal anti-inflammatory agents. The presence of such fistulae is suspected in patients complaining of weight loss, diarrhoea and faecal vomiting. Small fistulae may not be suspected when overshadowed by other complications of ulcer disease such as bleeding or perforated viscus. Medical management of benign gastrocolic fistulae may be indicated in some circumstances. Surgical treatment involves en bloc *resection, including the fistula, and surrounding colon and gastric segments.*

Keywords: Gastric ulcer, gastrocolic fistula

Gastrocolic fistula is a well-recognized complication of malignancies arising from the stomach or colon, and of surgery performed for benign disease of these organs[1–6]. Such fistulae arise rarely as complications of benign peptic ulcer of the stomach. We report four new cases of this complication, including one which presented with upper gastrointestinal haemorrhage before the fistula had become clinically apparent. In addition, we review 30 cases (including the four reported here) which have been described since the comprehensive review of this topic by Madsen *et al.*[6] 10 years ago. This review emphasizes that gastrocolic fistulae complicating benign gastric ulcer arise in close association with intake of steroidal and nonsteroidal anti-inflammatory agents. Some of these lesions may be amenable to medical management. Surgery is required in cases presenting with persistent physiological disturbance or those complicated by haemorrhage or perforation of a viscus.

Case report 1

A 62-year-old Caucasian man was admitted to the University of Utah Medical Center with a 1-year history of gastric ulcer. He had been intermittently compliant with medication regimens which included antacids and cimetidine. Two months before admission, his epigastric pain worsened and he experienced frequent episodes of nausea, vomiting, and watery diarrhoea, associated with a weight loss of 30 lb. He smoked approximately ten cigarettes per day and drank alcohol rarely. He had not ingested steroids, aspirin or other nonsteroidal anti-inflammatory agents. He had not previously required abdominal surgery. An abdominal computed tomography (CT) scan revealed a 6-cm infrarenal abdominal aortic aneurysm. Laboratory data on admission were normal. Upper and lower gastrointestinal radiographs demonstrated a communication between the posterior lesser curve of the stomach and the colon just proximal to the splenic flexure (*Figure 1*). At surgery, a truncal vagotomy was performed in conjunction with *en bloc* removal of the gastric antrum, the fistulous tract and a segment of transverse colon. Primary gastroduodenal and transverse colonic anastomoses were performed. Microscopic examination of the specimen revealed no evidence of malignancy. The patient recovered uneventfully and 4 weeks later underwent repair of his abdominal aortic aneurysm.

Case report 2

A 76-year-old Caucasian man was admitted to the Salt Lake City Veterans Administration Medical Center with a 2-day history of epigastric pain and faecal vomiting. His past medical problems included a long history of rheumatoid arthritis, for which he had been receiving oral steroid and nonsteroid anti-inflammatory agents. Smoking and alcohol abuse histories were not available. Physical examination

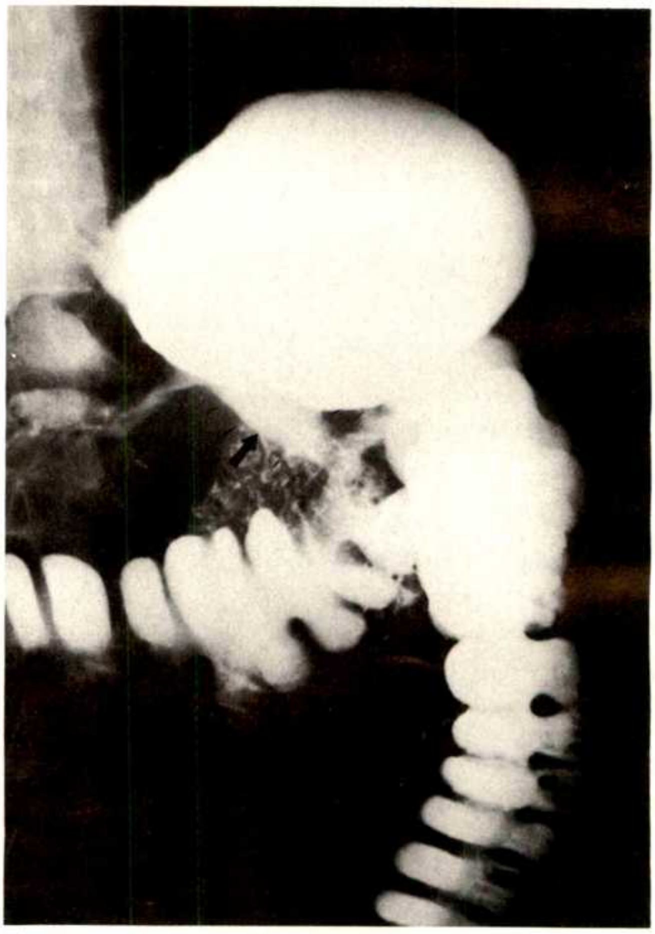

Figure 1 *A barium enema was performed in this patient (Case report 1), demonstrating a fistulous tract between the gastric antrum and the medial aspect of the splenic flexure of the colon*

0007-1323/89/121298-03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

revealed dehydration, malnutrition and guaiac-negative stool. Barium enema demonstrated a fistulous communication between the greater curvature of the stomach and the transverse colon just proximal to the splenic flexure. Gastroscopy revealed a 4 × 2 cm opening to the fistula which failed to heal after 5 weeks of management with bowel rest and parenteral nutrition. At operation, the duodenum and a loop of jejunum were adherent to the phlegmon but did not communicate with the fistula. An *en bloc* 75 per cent gastrectomy with segmental colonic resection was performed. A Roux-en-Y gastrojejunostomy was constructed and the two ends of the transverse colon were brought out as separate colostomies to the skin. The patient died on the fifth postoperative day owing to sepsis and multiple organ failure

Case report 3

A 66-year-old Caucasian woman was admitted to the John Cochran Veterans Administration Medical Center of St. Louis with a 10-day history of epigastric pain and melaena. In the past 20 years, she had intermittently taken antacids and H$_2$-receptor antagonists for a duodenal ulcer. In the past 5 years, she had ingested daily amounts of twenty to thirty 325 mg tablets of aspirin and four 600 mg tablets of ibuprofen for exacerbations of arthritis. She had smoked up to two packs of cigarettes per day for 40 years but had no history of alcohol or steroid use. Physical examination was remarkable for epigastric tenderness and melaenic stool. Admission laboratory data included a haemoglobin of 8·2 g/dl and a white blood cell count of 13·1 cells/mm^3 but were otherwise normal. Barium meal and upper gastrointestinal endoscopy revealed only a deep 2 cm ulcer crater on the dependent portion of the posterior greater curvature of the stomach

After admission, bleeding per rectum recurred and she required a transfusion of 6 units of blood. After bowel preparation, she underwent laparotomy. The greater curve of the antrum and distal corpus of the stomach were found to be adherent to the distal transverse colon. A 60 per cent gastrectomy and segmental transverse colectomy were performed, with truncal vagotomy, gastroduodenal anastomosis and primary transverse colon reanastomosis. Examination of the specimen revealed a fistulous communication between the stomach and resected transverse colon segment. No malignancy was identified in the specimen. The patient was discharged 2 weeks after operation, doing well.

Case report 4

A 34-year-old Caucasian woman was admitted to Barnes Hospital with a 12 to16 month history of watery diarrhoea. In the 6 months before admission, she experienced daily episodes of abdominal cramping, foul eructation, vomiting and, on occasion, stools containing red blood. For the previous 8 years she had been taking cimetidine for epigastric pain. A gastric ulcer had been documented 18 months previously by barium examination at another hospital She had smoked one pack of cigarettes per day since adolescence and ingested ten 325 mg aspirin tablets per day for headaches. She drank alcohol occasionally. Physical examination revealed a thin, dehydrated and pale young woman. The abdomen was not tender and the stool was guaiac-negative. Laboratory studies were not remarkable, except for a serum K$^+$ of 2·1 mmol/l. A serum gastrin level was elevated at 500 pg/ml. A gastrocolic fistula was demonstrated by barium meal examination and at endoscopy, communicating between the anterior aspect of the lesser curve of the stomach and transverse colon. The patient subsequently underwent *en bloc* resection of the fistula, distal two-thirds of the stomach and a segment of the transverse colon. A gastroduodenal anastomosis and primary reanastomosis of the transverse colon were performed. Histological examination of the specimen revealed no evidence of malignancy. Postoperative serum gastrin levels were undetectable. The patient was discharged 2 weeks after operation, doing well.

Discussion

In 1755, Haller described a case of gastrocolic fistula associated with abdominal cancer[1]. In 1897, Bec identified 62 such fistulae, 12 due to gastric ulcer[2]. In 1920, Firth reported the first case in the English language literature of gastrocolic fistula secondary to benign gastric ulcer[3]. A number of disease processes have been associated with gastrocolic fistula, including carcinomas and lymphomas of the stomach or colon, colonic diverticulitis, tuberculosis, syphilis, mycosis or inflammatory bowel disease[4–6]. In addition, such fistulae have been recognized as complications of surgical procedures of the stomach, distal transverse colon and splenic flexure[4–6].

As complications of benign gastric ulcer, such fistulae are uncommon. Akwari *et al.*[5] found four cases of this complication in reviewing a 10 year experience in which 957 patients underwent operation for benign gastric ulcer and its complications. Expanding on the work of Cody *et al.*[4] and Akwari *et al.*[5], Madsen *et al.* identified 77 cases of this complication, and added one of their own[6]. Since Madsen's review, 30 individually discussed cases (including the four reported here) were identified in English language journals[7–24]. It therefore seemed appropriate to update the discussion of the presentation and management of these fistulae, based on the cases reported in the past decade since the review of Madsen *et al.*[6].

Table 1 summarizes some of the presenting characteristics of these 30 patients. Two-thirds of these patients were female, in contrast to the nearly equal proportion of men to women in the cases collected by Madsen *et al.*[6] In addition, 11 of the patients were aged 50 or under, and ten of these were women. Approximately three-quarters of patients, in whom the history was available, were ingesting oral preparations of steroidal or nonsteroidal anti-inflammatory agents. Less than one-half of these patients gave a previous history of peptic ulcer or dyspeptic symptoms. Alcohol consumption and tobacco use were not uniformly recorded. Of the four patients described in the present report, three were currently smoking cigarettes and none had a history of alcohol abuse.

Table 2 summarizes the symptoms with which these 30 patients presented. As recorded previously[4–6], the most frequent symptoms included diarrhoea, weight loss, faecal vomiting and epigastric pain. Bleeding, manifested as haematemesis, melaena or haematochezia, was recorded in less than one-third of cases. Two cases[18,19] presented with perforation of the colon into the peritoneum. In almost 80 per cent of these cases, patients sought medical attention within 3 months of the onset of symptoms Thus, classically, gastrocolic fistulae are diagnosed in patients with faecal vomiting, but may be suspected in patients with unexplained abdominal pain, diarrhoea and a history of heavy ingestion of nonsteroidal or steroidal anti-inflammatory agents. Absence of previous peptic ulcer disease does not exclude the diagnosis.

The diagnostic studies routinely used in evaluating these lesions have included barium meal, gastroscopy, and barium enema. In six of 20 cases where it was used for diagnosis, the barium meal examination failed to document such fistulae.

Table 1 *Presenting characteristics of 30 reported cases of benign gastrocolic fistula from 1978 to 1988*

Male:female ratio	10:20
Mean age at presentation	
Males	61 years (range 46–77 years)
Females	52 years (range 26–80 years)
Previous history of ulcer disease/symptoms	15/29 patients (one patient was not recorded)
Ongoing use of steroids or NSAIDS (aspirin, motrin, indocin, naproxen)	18/24 patients (one patient used unidentified analgesics; five patients were not recorded)

NSAIDS, non-steroidal anti-inflammatory drugs

Table 2 *Presenting symptoms of 30 reported cases of benign gastrocolic fistula from 1978 to 1988*

	n	%
Weight loss	20	67
Onset or acute change in epigastric pain	19	63
Diarrhoea	19	63
Faecal vomiting	14	47
Melaena or haematochezia	8	27
Halitosis	6	20
Colonic perforation	2	7

Similarly, upper gastro-intestinal endoscopy failed to document evidence of fistula in five of 19 cases where it was performed for diagnosis as well as for biopsy of the lesion. In the 15 cases where it was used for diagnosis, however, barium enema detected the presence of gastrocolic fistula, even when the barium meal and gastroscopy had failed. Here in Case report 3, it seems likely that colonoscopy would have visualized the erythematous area surrounding the colonic mucosal end of the fistula. Barium enema or colonoscopy may thus be the most sensitive studies in visualizing these fistulae; nevertheless, gastroscopy with multiple biopsies of the ulcerated gastric aspect should be performed to exclude the presence of carcinoma in such lesions.

Since these lesions remain quite rare, the optimal approach to their management remains unresolved. Ekbom and Liedberg[16] and McCullough and Gregson[20], after carefully documenting the absence of malignancy in the fistula, treated their patients successfully with oral H_2-antagonists and by discontinuing ulcerogenic medications. No recurrences were observed in short-term follow-up Thus, rapid response to nonoperative measures may suggest that the patient's fistula and ulcer will heal without operation. When malignancy has been reliably excluded, expectant management may be warranted.

In 27 of the patients summarized here, operative approaches included excision of the fistulous tract locally (4 cases), or excision of the fistula with segmental colon resection and resection of the stomach including and distal to the fistula. In 16 patients, it was possible to reconstruct the upper tract with a Billroth I gastroduodenostomy emphasizing the absence of duodenal involvement in many of these inflammatory processes. In seven patients it was necessary to reconstruct with a gastrojejunostomy. Two perioperative deaths were recorded (Case report 2, the present report and Reference 22) among these 27 patients. Preoperative parenteral nutrition, bowel rest, use of intravenous H_2-receptor antagonists, and mechanical bowel preparations have been helpful in preparing patients for surgery and reducing morbidity of surgery for these lesions. To exclude malignancy in these lesions, it is necessary to excise the fistula, surrounding stomach and involved colon *en bloc*. Frozen sections of the fistulous tract should be submitted to exclude the possibility of malignancy.

One final issue in the management of these patients is illustrated by the recurrence of benign gastrocolic fistula recorded by Hollingshead *et al.*[13]. Their patient had uneventful recovery following surgery, but developed recurrence of a fistula 8 months later after resuming naproxen to control his severe arthritis. Perrault *et al.*[25] recently called attention to a subgroup of patients who presented with chronic recurrent gastroduodenal ulcers which ultimately failed to respond to medical management. Of the 4 patients described, three were young women, and all were under the age of 43. Ultimately, these patients were identified as surreptitious salicylate abusers. In view of the high rate of usage of steroidal or nonsteroidal anti-inflammatory agents in patients with gastrocolic fistulae, it may be prudent to monitor use of these medicines and perhaps measure salicylate levels in follow-up of some of these patients.

Time-related changes in characteristics of prognostic significance in carcinomas of the oesophagus and cardia

During 25 years (1960–84) 657 patients were operated on for squamous cell carcinomas ($n=230$)*, adenocarcinomas* ($n=399$) *or anaplastic carcinomas* ($n=28$) *of the thoracic oesophagus or cardia. The male:female ratio was 2·8:1 and the mean age was 66 years (range 22–91 years). Oesophagogastrectomy* ($n=514$) *was performed whenever technically possible. From the first (1960–64) to the last (1980–84) 5-year period the proportion of adenocarcinomas increased from 56 to 78 per cent* ($P<0{\cdot}001$)*, poorly differentiated cancers increased from 34 to 65 per cent* ($P<0{\cdot}0001$)*, and stage III–IV tumours increased from 72 to 88 per cent* ($P<0{\cdot}05$)*. Five-year cumulative rates(s.e.) were 11(3) per cent for operations during 1960–69* ($n=262$)*, 8(2) per cent during 1970–79* ($n=256$) *and 3(2) per cent during 1980–84* ($n=139$; $P<0{\cdot}05$)*. Hospital mortality rates (≤30 days) and 5-year cumulative survival rates(s.e.) were 6·5 per cent and 36(7) per cent* ($n=46$) *for stage I, 14·0 per cent and 21(4) per cent* ($n=114$) *for stage II, 17·8 per cent and 5(1) per cent* ($n=258$) *for stage III and 23·8 per cent and 3(1) per cent* ($n=239$) *for stage IV tumours* ($P<0{\cdot}05$ *and* $P<0{\cdot}001$)*. Well differentiated* ($n=70$) *cancers, those of medium differentiation* ($n=239$) *and poorly differentiated cancers* ($n=348$) *had 5-year survival rates(s.e.) of 24(5), 10(2) and 5(1) per cent, respectively* ($P=0{\cdot}0007$)*. Squamous cell carcinomas had a better prognosis than adenocarcinomas, even after stratification according to location of primary tumour. The 657 patients who underwent surgery constituted 50 per cent of a total of 1316 cases with cancer of the oesophagus and cardia reported from our catchment area during the study period. Frequency of surgery decreased with age. The annual incidence (number per 100 000 inhabitants aged 20 years or more) of adenocarcinomas of the lower oesophagus and cardia doubled to 5·9 in 1980–84, while that of squamous cell carcinomas tended to decrease (to 2·9). A successive worsening of long-term survival after surgery was explained by significant changes in cancer characteristics having pronounced prognostic significance. Over the 25 years the carcinomas changed towards the present pattern where poorly differentiated adenocarcinomas of the lower third of the oesophagus and cardia in stages III–IV have become predominant.*

Dr O. Lund

Patients with carcinomas of the thoracic oesophagus or cardia usually have advanced disease at the time of diagnosis[1,2]. Symptoms are non-specific but invariably present, and a mean weight loss of 10 kg is the rule[2]. The disease is most prevalent late in life and it is not surprising that prognosis has remained poor during the past 30 years[2,3]. In the absence of a major therapeutic breakthrough, oesophagogastrectomy remains the treatment of choice.

Using Cox's regression analysis a detailed risk estimation was previously performed on 657 patients operated on over a 25-year period[4]. A rather discouraging observation, which has not previously been reported, was made: namely that prognosis after surgery worsened progressively during the 25-year period. Since the operative year had no independent prognostic influence[4], the explanation should, in theory, be sought in time-related alterations in cancer characteristics. A clue was given by the fact that the annual incidence of cancers of the cardia in Denmark has shown a steady increase since the 1950s, while that of oesophageal cancers has shown a slight decrease[5].

The aim of the present report was to pinpoint possible changes in cancer characteristics during the 25-year period and to relate such changes to the postsurgical worsening of prognosis. Furthermore, this surgical series was compared with the background material which included 1316 cases with cancer of the oesophagus or cardia reported from our catchment area during the study period.

Patients and methods

Carcinomas

A total of 657 patients were operated on for carcinomas of the thoracic oesophagus or cardia from 1960 to 1984. Until recently the policy was to explore all patients, to resect the cancer whenever technically possible and to intubate (Celestin® tubes, Medoc, Gloucester, UK) the rest intraoperatively.

0007-1323/89/121301-07$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Operation was denied to only 45 patients during the study period. These patients are not included in the information presented here. The male:female ratio was 2·8:1, and the mean age was 66 years (range 22–91 years). Before operation, 615 patients had varying degrees of dysphagia, and 587 had experienced weight loss ranging from 1 to 35 kg (mean 10 kg). All patients had upper gastrointestinal symptoms. The patients have been described in detail previously[4].

Radiographs of the oseophagus (barium swallow) and oesophagogastroscopy with biopsy of the tumour were performed in all patients. Staging of the disease was mainly based on intraoperative TNM (tumour node metastasis) classification[6], including macroscopic and histological examination of the surgical specimens: stage I, $T_1N_0M_0$, stage II, $T_2N_0M_0$; stage III, $T_{1-2}N_1M_0$ or $T_3N_{0-1}M_0$; and stage IV, $T_{1-3}N_2M_0$ or $T_{1-3}N_{0-2}M_1$. The tumour locations were divided into four (oesophagus parts I–III, and cardia) as depicted in *Figure 1*. Location of the bulk of the tumour was used to discriminate between oesophagus part III and cardia in the case of extension between the two sites. There were 230 squamous cell carcinomas, 399 adenocarcinomas, and 28 anaplastic carcinomas (*Figure 1*).

Operative technique

The surgical technique has been described in detail previously[4,7]. In short, *en bloc* oesophagogastrectomy followed by careful mobilization of the stomach and intrathoracic end-to-end oesophagogastrostomy with deep oesophageal invagination was performed whenever possible ($n=481$). Roux-en-Y oesophagojejunostomy ($n=21$) was used after total gastrectomy and colon interposition ($n=12$) was performed when the stomach could not be sufficiently mobilized. Splenectomy was performed in 483 patients. Associated surgical procedures (stage III or IV exclusively) included liver resection ($n=2$), pancreatic resection ($n=27$), transverse colonic resection ($n=3$), adrenalectomy ($n=2$), pulmonary lobectomy ($n=6$), pulmonary subsegmental resection ($n=6$), tracheal resection ($n=4$) and diaphragmatic resection ($n=6$).

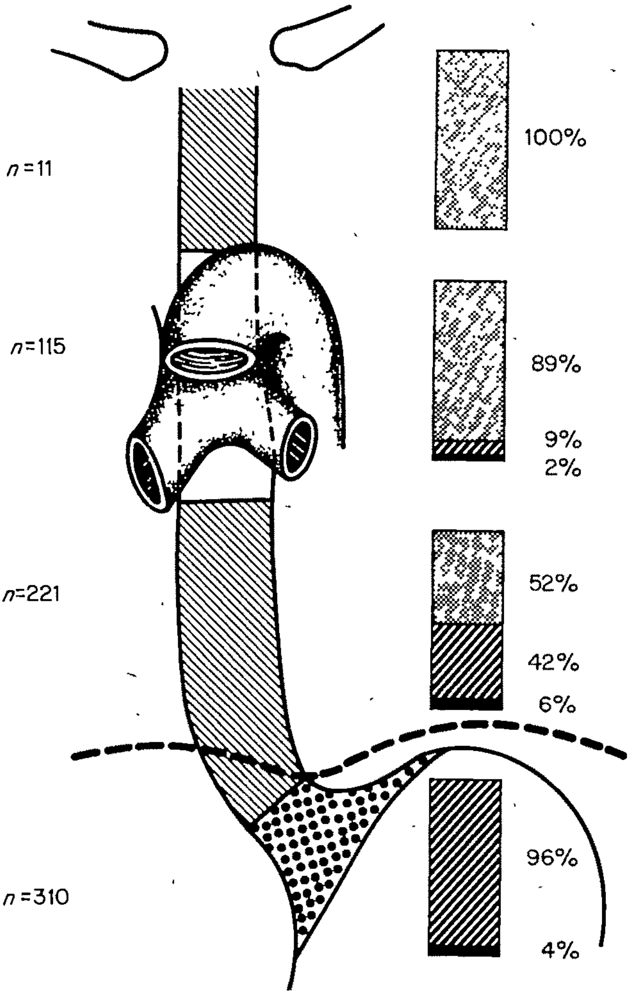

Figure 1 *Histological diagnosis in relation to location (surgical material). Thoracic inlet (indicated by the tips of the clavicles), upper margin of aortic arch, lower border of right main bronchus, and oesophagogastric junction separate location of the tumours into thoracic oesophagus parts I to III and cardia as indicated. The number of patients and percentage of the different histological types are given for each location. The distribution of histological types differed significantly between the locations* (P<0·0001). *Shadings represent* □, *squamous cell carcinoma;* ▨, *adenocarcinoma; and* ■ *anaplastic carcinoma*

Follow-up

In November 1986, 30 patients were alive from 1·8 to 24 years after the operation. Death certificates were available for all 627 deaths and autopsy reports for 306.

Background material

Since 1943 the Danish Cancer Registry has registered newly diagnosed cases of cancer in Denmark[8]. Data for all cases with cancers of the oesophagus and cardia reported from our catchment area during the study period (1960–84) were put at the authors' disposal by the Danish Cancer Registry, Institute of Cancer Epidemiology (Danish Cancer Society, Copenhagen). The tumours were classified according to the ICD-7 (International Classification of Diseases, WHO) code[9] before 1978 when the ICD-0 code[10], which includes detailed topographic and morphological information, was put into use. For the sake of continuity, the ICD-0 was translated into the ICD-7 system for the present study ICD-7 coding primarily infers that adenocarcinomas of the oesophagus, especially of the lower third, were classified as cardia tumours.

Statistical analysis

Comparisons between groups were performed using the standard χ^2 test or the one-way analysis of variance whenever appropriate. Cumulative survival rates were estimated using the Kaplan–Meier method and differences between curves judged with the log rank test and the Gehan (generalized Wilcoxon) test. All tests were computerized using the BMDP statistical package (BioMedical Data Processing Incorporated, Los Angeles, California, USA)[11]. The level of significance was chosen as 0·05. Quantitative data are given as mean(s.d.) or mean(s.e.m.). Cumulative survival estimates are given together with their standard error (s.e.)

Results

The histological types of the tumours are shown in *Figure 1* relative to location. The degree of histological differentiation was judged to be high in 11 per cent ($n=70$), medium in 36 per cent ($n=239$) and low in 53 per cent ($n=348$) of cases, without differences between squamous cell carcinomas and adenocarcinomas. Women ($n=171$) had squamous cell carcinomas in 52 per cent of cases, adenocarcinomas in 43 per cent of cases, and anaplastic carcinomas in 5 per cent of cases, compared with 29, 67, and 4 per cent, respectively, for men ($n=486$; $P<0·0001$).

The characteristics of the cancers changed throughout the study period, as shown in *Figure 2*. The fraction of patients with adenocarcinomas increased from 56 per cent in 1960–64 to 78 per cent in 1980–84, which was paralleled by an increase in the number of cardia tumours. Poorly-differentiated carcinomas showed a highly significant increase from 34 per cent in the first 5-year period to 65 per cent in the last; this was reflected by a rise in the fraction of patients with stage III or IV disease to 88 per cent in 1980–84. The mean(s.d.) duration of symptoms before diagnosis (6(4) months), the mean(s.d.) diameter of primary tumour mass (6·4(3·4) cm), and the sex and age distributions did not differ between the periods shown in *Figure 2*.

Resection of the tumour was accomplished in 514 patients (78 per cent) and was macroscopically radical in 368. The hospital mortality rate (≤30 days) was 19 per cent and the 5-year cumulative survival rate(s.e.) was 9(1) per cent. Overall long-term prognosis worsened during the period of study (*Table 1*), despite a decrease in hospital mortality (21 per cent for 1960–69, 18 per cent for 1970–79, and 15 per cent for 1980–84; not significantly different). The stage of the tumour was a strong predictor of long-term survival (*Figure 3*), with 5-year survival rates(s.e.) of 36(7) per cent for stage I, 21(4) per cent for stage II, 5(1) per cent for stage III and 3(1) per cent for stage IV ($P<0·0001$). Hospital mortality rate was 6·5 per cent ($n=3$), 14·0 per cent ($n=16$), 17·8 per cent ($n=46$) and 23·8 per cent, respectively, for stages

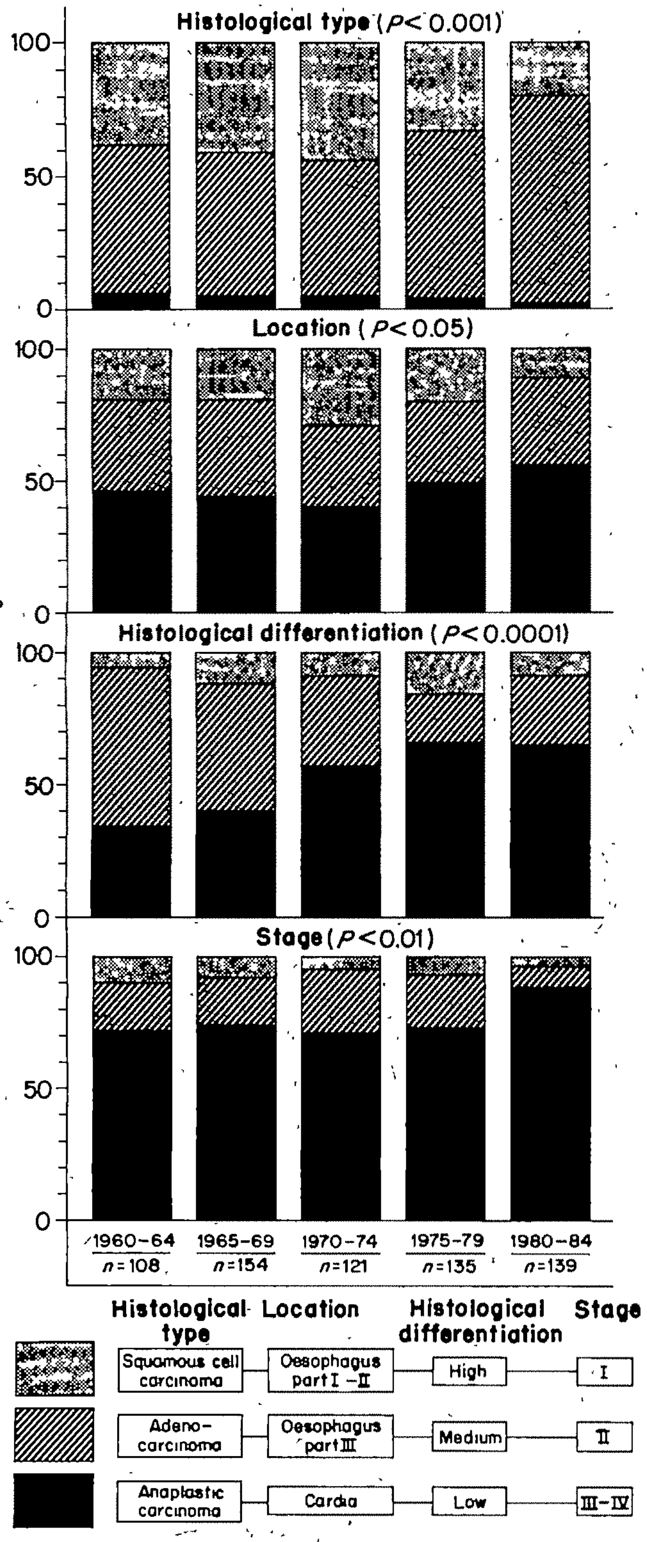

Figure 2 *Changes in cancer characteristics in relation to the five 5-year periods included in the present study (surgical material). Each modality (histological type, location, etc.) is divided into three subgroups with shadings as indicated*

I to IV ($P<0{\cdot}05$). Other important correlates of long-term survival are given in *Table 1*. Histological differentiation by itself exerted a pronounced prognostic influence with mean(s.e.m.) 5-year survival rates ranging from 24 per cent for well differentiated cancers to 5 per cent for poorly differentiated cancers. *Table 2* shows various characteristics of squamous cell carcinomas and adenocarcinomas separated according to location. T_3 tumours were most prevalent in squamous cell carcinomas of the first two parts of the oesophagus, while adenocarcinomas of the cardia had the highest frequency of organ metastases (M_1 class) and the largest tumour diameters. Adenocarcinomas of the oesophagus had an extremely bad prognosis compared with cardia tumours, while squamous cell carcinomas of the third part of the oesophagus had a better prognosis than those of the first and second parts. The fraction of patients who had a radical resection did not differ between the five groups of patients in *Table 2*.

The background material including 1316 cases is outlined in *Table 3* for the year of diagnosis (and operation). The annual incidence of oesophageal cancers showed a decreasing tendency during the study period while that of cardia cancers doubled. In total almost, 50 per cent (equivalent to the present surgical series) were operated on (*Table 3*). The frequency of surgery

* Classified according to an expanded version of the ICD-7 code[9] inferring that adenocarcinomas of the oesophagus, especially of lower third, were classified as cardia cancers. ICD-0 coding[10] which includes detailed topographic and morphologic information was used from 1978. For the present purpose, ICD-0 code (1978–84) was translated into ICD-7 code. Five patients with tumour of the cervical oesophagus were excluded; † Number of cases per year per 100 000 inhabitants aged 20 years or more of catchment area at midpoint of each 5-year period (Statistical Yearbooks, Danmarks Statistik, Copenhagen 1960–84). The modifications in catchment area and in inclusion and exclusion of reported cases noted above also dictated catchment populations (one for oesophagus, one for cardia, reduction in area from 1970); ‡ See *Figure 1*; § In order to make classification comparable to that of total population adenocarcinomas of lower third of oesophagus (see *Figure 1*) were classified under 'Cardia'. (The data were put at our disposal by courtesy of the Danish Cancer Registry, Institute of Cancer Epidemiology, Danish Cancer Society, Copenhagen. The counties of Aarhus, Viborg, Ringkoebing, and North Jutland were considered. Cardia cancers from Ringkoebing County were excluded, since these patients were managed locally throughout the period. Cases from North Jutland County were excluded from 1970 onwards, since the local County Hospital took over treatment in January, 1970.)

varied both with location of the tumour and with the year. Use of the topography given in *Figure 1* for the surgical patients indicated that a higher fraction of oesophageal than cardial tumours underwent operation. This was reversed when the ICD-7 topography used for the background material was also used for the surgical patients (*Table 3*). In both instances, the frequency of surgery during the study remained fairly constant for cardia tumours, while the frequency for oesophageal tumours increased until the mid-1970s whereafter it decreased. *Table 4* shows characteristics of both the background material and of the present surgical cases. The frequency of surgery according to age group was: 59 per cent for patients ⩽49 years ($n=66$); 65 per cent for patients 50–59 years ($n=171$); 68 per cent for patients 60–69 years ($n=355$); 47 per cent for patients 70–79 years ($n=434$); and 20 per cent for patients ⩾80 years ($n=290$; $P<0{\cdot}0001$). The frequency of surgery was 39 per cent for women ($n=434$) and 55 per cent for men ($n=882$; $P<0{\cdot}0001$). Histological diagnoses were available from 1978. When the ICD-7 topography was used for the present surgical material (*Table 4*) the distribution of histological diagnoses in the oesophagus and cardia of background and of surgical cases were comparable. In total, the surgical group included a smaller fraction of squamous cell carcinomas and a higher fraction of adenocarcinomas. During 1978–84 the frequency of surgery was 36 per cent for squamous cell carcinomas ($n=132$) and 56 per cent for adenocarcinomas ($n=258$; $P<0{\cdot}001$).

Discussion

The present surgical patients constitute 94 per cent of all patients referred to the authors' department over 25 years. This was possible because of the aggressive surgical approach, aiming at resection whenever possible, even in disseminated disease. This approach probably also dictated that a relatively high proportion of patients (50 per cent) from our catchment area were operated on and are thus included in the present surgical series. In a recent detailed survey covering more than 6000 cases with oesophageal cancer reported to the Birmingham and West Midlands Cancer Registry, UK, 38 per cent underwent surgery[12]. Depending on whether the topographical classification of the present study (*Figure 1*) or an approximation to the expanded ICD-7 code[9] was used, the frequency of surgery in this study was 55 or 45 per cent for the oesophagus and 40 or 59 per cent for the cardia (*Table 3*). The true figures probably lie in between (i.e. those that would have resulted if it had been possible to use the ICD-0 code[10], which offers detailed topography, on the background material).

The annual incidence of cancers of the cardia in our catchment area showed a steady increase during the study period, which is fully in line with national developments[5]. The declining incidence of oesophageal cancer in the study area also parallels national findings[5]. Given the ICD-7 coding[9] of the background material, inferring especially that lower-third

oesophageal adenocarcinomas were classified as cancers of the cardia, it follows that the annual incidence increase predominantly affects adenocarcinomas of both the lower oesophagus and cardia, while oesophageal squamous cell carcinomas show a declining incidence. Comparable developments for the oesophagus were reported from the Birmingham and West Midlands Cancer Registry[12]; only adenocarcinomas, predominantly those of the lower oesophagus, showed a significant increase in incidence during a 25-year period (1957–81).

Age distribution in the background material and of the patients who were operated on was largely comparable except that a significantly lower fraction of the older patients underwent surgery. Background patients with oesophageal cancer were older than cardia cases, mainly because of a higher fraction of patients in the over 80 age group (*Table 4*). Thus, the age factor probably explained why a lower fraction of patients with squamous cell carcinomas than of those with adenocarcinomas underwent surgery. The more equal distribution between men and women in the former group together with the age factor may explain why the frequency of surgery was lower for women than for men.

The fact that no competitive treatment was available for the patients in this series, together with the above considerations, clearly indicates that patients who did not undergo surgery, contrary to being prognostically better off (in terms of factors such as age and cancer stage), were probably worse off than the surgical patients. With this in mind, it may to some extent be permissible to extrapolate changes noted in this surgical series to the wider population of patients with these cancers

The time-related changes in cancer characteristics noted in the present surgical patients, which paralleled the steady increase in annual incidence of adenocarcinomas of the lower oesophagus and cardia, seem unequivocal. From the first to last 5-year period the fraction of patients having adenocarcinomas increased from a little more than 50 per cent to almost 80 per cent. The most massive change was seen in the case of histological differentiation: the fraction of poorly differentiated carcinomas doubled from one-third in the first 5-year period to two-thirds in the last. The cancers thus showed a clear cut change towards poorly differentiated adenocarcinomas of the lower oesophagus and cardia, the vast majority of which had reached stage III or IV at the time of diagnosis. Similar data have to our knowledge not been published previously.

The distribution of histological types according to location (*Figure 1*) followed the general trend, although the high fraction of adenocarcinomas of the third part of the oesophagus is at variance with most other reports. Adenocarcinomas have been reported to constitute less than 12 per cent of primary oesophageal cancers[12–15], but the mode of classification, of course, may have a massive influence (*Table 4*). A histological re-evaluation of a possible gastric origin of the oesophageal adenocarcinomas in our series, or of origin from columnar lined (Barrett's) oesophagus or oesophageal glands, was not possible given the retrospective nature of our study However, several findings indicated that the high fraction of oesophageal adenocarcinomas here may have some bearing. The 5-year survival rate for adenocarcinomas of the lower third of the oesophagus was no more than 2 per cent (*Table 2*). None of the ten patients with adenocarcinomas of the upper two parts of the oesophagus survived 5 years. These figures should be compared with a 5-year survival rate of 9 per cent for adenocarcinomas of the cardia. Thus, the latter cancers appeared to have a better prognosis than oesophageal adenocarcinomas, despite the fact that degree of histological differentiation, lymph node involvement, stage of the disease and age of the patients did not differ between these three groups. Contrary to what might have been expected from the prognostic differences, a higher fraction of adenocarcinomas of the cardia had extended through the wall (T_3 tumour) and had organ metastases than oesophageal adenocarcinomas. Furthermore, the bulk of the tumour was used to discriminate between the third part of the oesophagus and cardia in cases of extension between the two sites; as the diameters of the cardia tumours were significantly larger than those of oesophageal adenocarcinomas, it follows that the majority of bulky tumours not clearly demarcated in the cardia were actually classified as tumours of the cardia. Tumours of the cardia being larger than the other adenocarcinomas also contrasts with what should have been expected, given the rather strong prognostic influence of tumour size. Cardial and oesophageal adenocarcinomas in the present study thus showed completely different behaviour, indicating that they probably had different aetiological origins, and that the unusually high proportion of tumours in the lower oesophagus is a reliable finding, which all in all puts further stress on the time-related changes previously discussed The present study does not allow comments on possible aetiological factors underlying these changes. In contrast to squamous cell carcinomas, with their well known relation to alcohol intake and tobacco smoking[5], there is no firm knowledge about the aetiology of adenocarcinomas of the oesophagus and cardia[5,13] except for the connection with the relatively rare Barrett's oesophagus[16,17]. Since the Second World War, when the national annual incidence of cancers of the cardia began to rise steadily, the general socioeconomic status of the Danish population has shown a steady rise to a relatively high level. Whether this development has brought about aetiological consequences affecting adenocarcinomas of the oesophagus and cardia is, however, purely speculative.

The grim prognosis of oesophageal adenocarcinomas in the present study is in full accordance with other reports[13,18]. As also noted by Mathiesen *et al.*[1], Earlam and Cunha-Melot[2] and Griffith and Davis[19], but contradicted by others[20,21], it was found here that squamous cell carcinomas had a better prognosis than adenocarcinomas. Location also modified prognosis for the squamous cell carcinomas; long-term survival was somewhat better for the third part of the oesophagus compared with the upper two parts. Almost 50 per cent of the latter patients had T_3 tumour, while organ metastases were more prevalent among those with tumours in the lower third of the oesophagus. Histological differentiation, lymph node involvement and stage did not differ between the squamous cell carcinomas of the two locations. The same tendency for a better prognosis of squamous cell carcinomas of the lower third of the oesophagus relative to the upper two-thirds has been found in several other reports[14,19,22,23]. Akiyama *et al.*[23] noted a higher prevalence of lymph node involvement in tumours of the upper oesophagus, which is at variance with the findings of the present study. Launois *et al.*[24] reported a superior prognosis for middle third squamous cell carcinomas compared with those of the lower third. However, their study differed from the present one in one important aspect: two-thirds of their patients had well differentiated tumours[24].

Patient age and the diameter of the primary tumour mass had a fairly strong prognostic influence, which has also been shown elsewhere[21]. The younger patients, aged 55 years or below, had a slightly poorer prognosis than the following 10-year cohort. Thereafter age showed the usual inverse relationship with survival probability. A tumour diameter of 3 cm or less predicted a 5-year survival rate of 15 per cent. Having exceeded 3 cm, the 5-year survival rate dropped to 8 per cent without substantial influence of a further increase in tumour size. These relationships did not influence the successive worsening of overall prognosis in this study, because patient age and the diameters of primary tumour remained unchanged during the study period.

Stage was a powerful predictor of prognosis in the present study, as is reported by several authors[15,20,25]. Stages III and IV, constituting almost 90 per cent of the surgical patients in 1980–86, had 5-year survival rates of only 5 and 3 per cent, respectively.

The degree of histological differentiation by itself exerted a highly significant impact on prognosis. The 5-year survival rate dropped from 24 per cent for well differentiated cancers to 5 per cent for poorly-differentiated cancers. As the degree of differentiation did not differ between adenocarcinomas and squamous cell carcinomas, or between the different locations, it may be concluded that the increase in poorly-differentiated cancers during the period of the present report was valid, irrespective of histological type and location of the tumour. The pronounced prognostic influence of degree of differentiation excludes the possibility that the changes with time were related to differences in interpretation of the histological sections by different pathologists. Thus, this evolution towards poorly differentiated cancers, together with the resultant increase in the fraction of patients having stage III or IV disease, fully explains why long-term survival worsened progressively during the period of the present study. The 5-year survival rate dropped from 11 per cent for patients operated on during 1960–69 to no more than 3 per cent for those operated on during 1980–84, where almost 90 per cent had stage III or IV disease and two-thirds had a poorly differentiated carcinoma. This worsening of long-term prognosis stands out even more clearly given that the hospital mortality rate actually fell, although statistically insignificantly, from 21 per cent for the 1960s to 15 per cent for the 1980s. This drop in hospital mortality rate should be seen relative to the concomitant increase in the prevalence of patients with stage III–IV disease; these patients had significantly higher hospital mortality rate than those with stage I–II disease.

In another study based on the present surgical material a prognostic index based on T-, N-, and M-classification, together with age and variables underlying general preoperative patient status, such as pre-existing heart and lung diseases, has been developed[4]. This allowed identification of a large group of patients (40 per cent of all patients) where none survived 3 years[4]. As these patients also carried the highest postoperative complication rate, the authors now advocate non-operative palliation in such patients[4]. Given the time-related changes noted in the present report, the fraction of these high-risk patients increased well beyond 50 per cent in 1980–84.

Discouraging as these changes in cancer characteristics are in themselves, they should be looked upon with even greater seriousness given the absence of a therapeutic breakthrough in management of carcinomas of the oesophagus and cardia during the past decades. Recent experience seems to indicate a beneficial influence of combined surgery, chemotherapy, and irradiation on oesophageal squamous cell carcinomas, but only in localized tumours[26]. Therefore, in the present setting, where poorly-differentiated adenocarcinomas in stage III and IV dominate, there seem to be only two alternatives. One is to accept that treatment in the majority of cases can aim only at palliation of dysphagia, which may be performed with a low early mortality rate using endoscopical laser recanalization[27,28] or intubation[29,30]. The other alternative is to diagnose the cancers at earlier stages using such methods as exfoliative cytology during mass screening programmes[31]. Such programmes are, however, not economically practicable in the western world given the relatively low incidence of the disease.

Protein electrophoresis of diagnostic peritoneal lavage fluid has been shown in experimental work to be a marker of hollow viscus injury. In order to ascertain the value of this investigation in penetrating abdominal trauma, we conducted a prospective study, over a 4-month period, involving 35 patients with stab wounds to the abdomen whose initial clinical examination was equivocal. The results of electrophoresis were compared with the standard quantitative criteria for diagnostic lavage and the operative findings. Protein electrophoresis was found to be a more sensitive and specific marker of significant intra-abdominal injury than the standard quantitative criteria.

Keywords: Diagnostic peritoneal lavage, protein electrophoresis, penetrating abdominal trauma

Diagnostic peritoneal lavage (DPL) has become the cornerstone of investigation in patients with blunt abdominal trauma in whom clinical assessment is equivocal. Introduced by Root *et al.* in 1965[1] and expanded upon by the same group in 1967[2], it has been shown repeatedly to be a safe and extremely sensitive adjunct to physical examination[3–6]. Numerous attempts have been made to quantify the degree of staining of the lavage effluent and to determine what should constitute a positive return[7–10]. The quantitative standard criteria were introduced nearly 20 years ago[11,12] and, despite minor modifications[13–15], are still in use today (*Table 1*).

Despite obvious success in cases of blunt abdominal trauma, the role of DPL in penetrating trauma remains controversial[16–18]. False negative DPL results as high as 30 per cent have been reported using the standard criteria[19] and suggested red cell counts as indicators for laparotomy vary from 1000 to 100 000 cells/mm^3 (References 20–22). Erroneous results have also been encountered using the standard value for white cell counts[2,23].

The use of protein markers as an aid to the diagnosis of intestinal injury was first suggested from experimental work by Bar-Or in 1983[24]. The purpose of our study was to evaluate the sensitivity of these markers in cases of suspected penetrating abdominal stab wounds and to compare their usefulness with that of the standard criteria for DPL.

Patients and methods

During the 4-month period, from March to June 1988, at the King Edward VIII Hospital, Durban, 121 patients were treated for stab wounds to the abdomen. Following triage, patients were assigned to one of three groups on the basis of physical examination conducted by one of the authors (M.M.). Group 1 ($n = 49$) comprised those patients who required immediate laparotomy (unexplained hypotension, disembowelment, generalized peritonitis, omental protrusion through a chest wound). Group 2 ($n = 37$) comprised patients with no clinical evidence of peritoneal penetration (tenderness confined exclusively to the stab wound, normotension, afebrile). This group underwent repeated clinical assessment. Group 3 comprised those patients with equivocal clinical findings in whom significant injury could neither be confirmed nor excluded on clinical examination alone (tenderness distant from stab wound but without generalized peritonitis, mild pyrexia, normotension). This group of 35 patients underwent preoperative DPL and forms the basis of this study.

There were 32 male patients and three female patients, with an age range of 16–58 years (mean 29 years). Stab wounds involved the flank in seven patients, was between nipple line and costal margin in three, above the umbilicus in 14, below the umbilicus in seven, and involved the back in the remaining four.

DPL was performed using the guidewire method described by Lazarus and Nelson[25] with prepacked sterile kits (American Pharmaseal Company, LNT 9000, Valencia, California, USA). One litre of normal saline was instilled, with a minimum of 50 ml retrieval by gravity necessary to ensure adequate sampling. An adequate quantity was achieved in all cases. Samples of the lavage fluid were then analysed by the haematology laboratory using an automatic Coulter counter (Counter Electronics, Itialeah, France) on unconcentrated lavage fluid. Protein analysis was performed by the biochemistry laboratory using a Beckman Paragon® serum protein electrophoresis kit (Beckman Instruments Inc., Brea, California 92621-6209, USA) after concentration of the lavage fluid in a Minicon-B concentrator (Amicon, Danvers, Massachusetts, USA).

After DPL, all patients were submitted to laparotomy, the surgeon performing the operation being unaware of the lavage results. The operative findings were then compared with lavage values for proteins, white cell count and red cell counts. Strict criteria were used to define positive and negative laparotomies. A positive laparotomy was defined as one in which surgical repair of a damaged viscus was required in order to prevent complications. A negative laparotomy was defined either as one in which there was no peritoneal penetration, or in which, despite penetration, haemoperitoneum, or solid organ injury, no surgical repair was required to effect cure.

Sensitivities, specificities and predictive values were calculated for white cell counts using 500 cells/mm^3 as diagnostic of significant injury, and for various values of red cell counts previously proposed as being diagnostic. Statistical analysis for protein fractions was done using an unpaired Student's t test.

Results

Two patients in group 1 had a negative laparotomy using the aforementioned criteria. One presented with hypotension and

Table 1 *Standard quantitative criteria for diagnostic peritoneal lavage in blunt abdominal trauma*

Aspiration of 5 ml or more of frank blood
White blood cell count > 500 cells/mm^3
Red blood cell count > 100 000 cells/mm^3
Amylase of > 200 units/100 ml
Bile stained effluent
Positive Gram stain
Food particles in effluent
Recovery of lavage fluid via Foley catheter or intercostal drain

at laparotomy a large laceration which had stopped bleeding was found in the right lobe of the liver. The second patient presented with omental protrusion through a stab wound immediately above the left costal margin. At laparotomy no communication with the pleural cavity could be found, nor was there any intra-abdominal visceral injury. Not one patient in group 2 required operative intervention. In group 3, there were 26 positive laparotomies and nine negative laparotomies (*Table 2*).

Correlation between operative findings and cell counts are shown in *Table 3*, along with sensitivity, specificity and predictive values. Protein fraction measurements for positive and negative laparotomies are shown in *Table 4*.

Cell counts

White blood cells. Although showing a reasonable sensitivity and positive predictive value, the specificity and negative predictive value of the white cell count is poor. The high false negative rate was due, in the main, to four missed pure diaphragmatic injuries, the remaining two missed injuries being a retroperitoneal colonic perforation and a single jejunal perforation. The four false positives were due to moderate haemoperitoneum with no surgically correctable lesion in three patients, and to a completely negative laparotomy with no peritoneal penetration in the remaining patient.

Table 2 *Operative findings in 35 laparotomies*

Pancreas	1		

Red blood cells. From *Table 3*, it can be seen that the use of higher red cell counts decreases the sensitivity and negative predictive value while increasing the positive predictive value and specificity of the test. Use of the standard proposed criterion of 10^5 red cells/mm^3 would have resulted in four missed intestinal perforations (one gastric, one colonic, two jejunal) and four missed diaphragmatic tears out of the six encountered in this series, a false negative rate of 23 per cent overall. Conversely, the use of a low red cell count, 5×10^3/mm^3, would have resulted in an unacceptably high rate of false positives (26 per cent) and subsequent negative laparotomies.

Protein fractions

Comparison of protein fractions in lavage fluids between those patients with injury requiring repair and those without surgically correctable lesions showed statistical significance for all fractions examined (*Table 4*). The α-2 fraction appeared to be the most sensitive indicator of major injury. Overlap between observed ranges in the positive and negative laparotomy groups did not occur in the α-1, α-2, β or γ protein fractions, but was seen on three occasions in the albumin and total protein fractions. The three patients in the positive laparotomy group whose values fell into the observed range in the negative group had all sustained injuries to the diaphragm without other intraperitoneal visceral injury. No significant difference with respect to protein fractions was found between those patients with solid organ injury requiring repair and those with hollow visceral injury.

Discussion

Negative laparotomy for abdominal trauma has a reported mortality rate of up to 6 per cent and a complication rate of between 19 per cent and 23 per cent[26]. As a result, in most centres that manage large numbers of trauma patients, mandatory laparotomy for stab wounds to the abdomen has been superseded by a selective policy[27–31]. Since Shaftan first suggested selective intervention using repeated clinical examination[32], the exploratory laparotomy rate has fallen dramatically[27–34]. Further reduction in the negative laparotomy

Table 3 *Correlation between blood cell counts in diagnostic peritoneal lavage and operative findings*

Cells/mm^3	True positive	True negative	False positive	False negative	Sensitivity (%)	Specificity (%)	Predictive value of a positive test (%)	Predictive value of a negative test (%)
White cells								
500	20	5	4	6	77	56	83	45
Red cells								
5000	26	0	9	0	100	0	74	100
10000	25	3	6	1	96	33	81	75
20000	24	5	4	2	92	56	86	71
100000	18	7	2	8	69	78	90	47

Table 4 *Protein fraction measurements in diagnostic peritoneal lavage in positive and negative laparotomy groups*

	Positive laparotomy		Negative laparotomy		
Protein fraction (g/l)	Range	Mean (s.d.)	Range	Mean (s.d.)	P
α-1	0·035–1·00	0·36 (0·28)	0·015–0·030	0·022 (0·008)	<0·001
α-2	0·25 – 1·75	0·76 (0·48)	0·002–0·04	0·026 (0·012)	<0·001
β	0·20 – 7·50	1·45 (1·71)	0·02 –0·06	0·036 (0·014)	<0·002
γ	0·30 – 4·00	1·62 (1·16)	0·04 –0·08	0·063 (0·015)	<0·001
Albumin	0·18 –10·70	3·80 (2·78)	0·23 –1·60	0·51 (0·41)	<0·001
Total protein	0·26 –18·70	8·02 (5·52)	0·33 –2·90	0·82 (0·79)	<0·001

rate has been achieved by the use of local wound exploration combined with diagnostic peritoneal lavage, should the former prove positive[28,33]. However, no uniform agreement has been reached with regard to standardization of DPL in penetrating trauma and diagnostic cell counts vary considerably from centre to centre[15,19,20–22,28,33,35]. No one set of standard criteria for cell counts can be reliably proposed owing to the wide spectrum of potential injuries. Values that recognize one specific injury, e.g. diaphragmatic penetration[35], are too sensitive for general use, while higher red cell counts will miss significant injuries. Similarly, elevated white cell counts may only arise with peritoneal irritation and injuries producing minimal inflammatory changes in the peritoneum will go unrecognized. Falsely elevated white cell counts may result from autologous blood transfusion into the peritoneal cavity, as witnessed by Root and colleagues[2]. In addition, animal models have shown that leucocyte responses greater than 500 cells/mm^3 can be obtained with minimal peritoneal interference by using unsterile lavage catheters[23].

Previous experimental work showed significant levels of protein fractions, especially the β globulin fraction, in DPL fluid in cases of intestinal injury[24]. Our own clinical study has found that in penetrating trauma, there is a highly significant difference in all protein fractions between those patients who require surgical intervention and those with either minor injuries or no peritoneal penetration.

Electrophoresis of lavage fluid requires 40–60 min to perform. For this reason, clinical examination should remain the mainstay of assessment in cases of penetrating torso trauma. Those patients who exhibit obvious signs of intraperitoneal injury should be submitted to laparotomy without further specialized investigation. Likewise, those patients whose initial clinical assessment shows no evidence of peritoneal penetration may safely undergo repeated examination on a 2-hourly basis[30]. Although the numbers in this study are small, statistical analysis indicates that protein electrophoresis of DPL in patients with equivocal clinical findings may help identify those who require surgical intervention for their injuries. Electrophoresis of the lavage effluent in this group of patients could, by the time repeat clinical examination was appropriate, indicate whether surgical intervention is required or not, thus avoiding both unnecessary delay and negative laparotomies.

Protein electrophoresis relies neither on peritoneal contamination nor extravasation of red blood cells and appears to be a more sensitive and specific investigation than cell counting. Its use in the future, if specific ranges for significant and insignificant injury can be reliably documented, may reduce the number of unnecessary operations and prevent avoidable delay with its ensuing complications in those who require surgery for their injuries.

Most surgeons are impatient perfectionists. They have little time to spare for reading outside their subjects, and what reading they do is probably done while travelling, between operations, or late at night. It is perhaps not surprising, therefore, that they are prepared to tolerate – both in their reading and their writing – convoluted prose, sloppy analyses, careless presentations, and unfounded conclusions. A proportion of the manuscripts submitted for publication in *The British Journal of Surgery* during the past few months contained one or more of these defects.

Some of the examples were minor – for example, miscalculation of percentages, spelling mistakes and the use of unexplained abbreviations. Some, however, were more serious and could have undermined the editors' determination to maintain the highest standards of ethical and scientific integrity and surgical reliability. Some authors did not supply enough information for readers to place any reliance on either their results or their conclusions; some quoted percentages inappropriately, given the smallness of their samples, and some did not differentiate between statistical significance and biological relevance, coming to conclusions that were potentially misleading

This article is not a criticism of the editors. Their principal tasks are to publish ideas, techniques and trials that are interesting and may have a potential for altering clinical practice, as well as controversial statements and authoritative reviews. As most surgeons are not trained in techniques of presentation it does mean that both scientific and technical editors have to spend a lot of time trying to eliminate errors before the papers are printed; their burden would be lighter if authors took the trouble to submit manuscripts that were free from at least the most obvious solecisms.

In this paper I illustrate some of these points, and suggest remedies for the grossest errors of presentation. I must emphasize that many of the defects were corrected before the papers were published and that my analysis was of the manuscripts.

Major faults in presentation

Ethics

Most authors reporting controlled trials were careful to point out that either the trial had been approved by their local ethics committee, or the patients had given *informed* (my italics) consent; the extent of information given, and particularly the way in which the process of randomization was explained to patients, however, was usually not mentioned. This is not of particular moment if the experimental procedure being studied is of no pressing concern to the patient, but it is a matter which must be considered.

Inadequate definitions

Several studies, which had the potential for altering clinical practice, were rendered less effective than they might have been because they either omitted, or gave inadequate, definitions of events, methods or end points. Such definitions are particularly important in multicentre studies. For example, Cahill *et al.*[2] reported a study of sutureless colonic anastomosis using a biofragmentable ring. This was carried out in six countries and the authors stated that 'Anastomotic leakage, wound infection and subacute obstruction rates reported are those detected clinically' That is all For all the reader knows one hospital could have defined wound infection as redness around the wound, while another accepted only total breakdown.

Clason *et al.*[3] argued in favour of the centralization of vascular surgery to units with a vascular interest, by comparing morbidity and mortality during two periods of time for patients with acute ischaemia of the lower limb. They did not, however, give full details about the comparability of the two groups for some of the risk factors known to have adverse effects on such patients It is possible that the improvement in morbidity between the two periods could have been caused by an imbalance of the proportions of smokers, or diabetics, or older patients, in one of the groups.

Sarin and Lightwood[4] reported an audit or 66 upper and 65 lower gastrointestinal anastomoses constructed with a continuous single layer polyglycolic acid suture Their complication rates were acceptable, but they failed to define what they meant by wound infection and anastomotic breakdown. Readers might also have appreciated reference to earlier experimental studies of healing after single layer continuous suturing of the colon[5].

It is a habit among authors who have made a study of a subject to assume that everybody else knows as much about it as they do. Indeed that probably applies also to the referees of papers, as they have been chosen by the editors because of their special interest. It would have helped general readers, however, to understand the paper by Fisher *et al.*[6], had they been told what the 'functional score' was, and the paper by Ashley *et al.*[7] would have been clearer if 'Bloom's grade' had been explained.

Retrospective studies are useful, particularly when rare diseases or uncommon operations are reported. They are marred, however, if the method of acquiring the data is not mentioned. It is a brave man who states that he studied *all* patients with a particular condition[8,9]; data collected for administrative purposes are well known to be inadequate and inaccurate[10], and audits based on these data are seldom complete[11].

Type III errors

Type III errors were first described by Condon[12] who defined them as ways in which 'the conclusions drawn are not supported by the data presented' Murray *et al.*[13] implied in the first sentence of their Discussion that their technique of ultrasonic

0007-1323/89/121311-04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

shock wave disintegration of gall stones was clinically useful; what they had actually shown was that they had fragmented 55 stones in the laboratory at wave lengths that had been shown to be safe (in rats).

Taylor and Morris[14] committed a Type II and a Type III error when they referred to a trend ('Praziquantel alone showed a trend to being more effective [in gerbils] than albendazole at reducing the number of [hydatid] cysts'). What they really meant was that they had not studied enough gerbils to prove or disprove the null hypothesis, and they failed to emphasize that gerbils may react differently from people.

Several authors equated statistical significance with clinical relevance or biological importance. Some journals now require that confidence intervals are stated instead of (or as well as) P values to minimize this error, but the idea that '$P<0{\cdot}05$ = the truth' is firmly ingrained. For example, Fisher *et al.*[6] claimed that 13 constipated patients who were improved by operation (we are not told what operation) had lower preoperative anxiety scores and lower depression scores than eight similar patients who were not improved. Despite achieving statistical significance ($P<0{\cdot}05$ and $P<0{\cdot}02$, respectively) the overlaps between the groups (scores 3 to 14 compared with 10 to 19, and 2 to 12 compared with 5 to 11) were such that it is obvious that there were no determinant differences between the groups for either score. There is also a move by some statistical advisers to ban the use of the abbreviation 'NS' on the grounds that the idea that 'NS = not significant' therefore 'not so' is as bad as '$P<0{\cdot}05$ = the truth'.

Leahy[15] deserves credit for putting forward a new technique (laparoscopic appendicectomy) that can reduce the length of time spent in hospital after operation. We are told that the patients were generally fit to leave hospital the day after operation, and that they returned to work or normal activities within a week. All well and good had he left it there, but in his Discussion he stated that: 'The absence of postoperative adhesions is important especially in female patients.' This is a far reaching conclusion on the experience of four patients, neither the sex nor the length of follow-up of whom are mentioned. Adhesions are less formidable after laparoscopic sterilization than after laparotomy, but it is by no means certain that this will also be the case after appendicectomy.

Moving up the gastrointestinal tract, and also into the fashionable area of allotting 'scores' to patients' degrees of risk, Schein and Gecelter[16] maintained that it is possible to use the APACHE II score to stratify patients with upper gastrointestinal bleeding on admission to hospital into high and low risk groups so that the best treatment can be chosen for each patient. Their survey was carried out retrospectively (though we are told the method by which the information was garnered) and the conclusions were not validated prospectively in a comparable group of patients. How many methods and ideas that seemed proved by a retrospective survey have bitten the dust when subjected to the objectivity of a prospective validation? Not only that, but Knaus himself would be the first to admit that APACHE II was not designed to stratify individual patients before operation; it was designed to allow comparison of the results of treatment within single intensive care units, or among those in different hospitals. In addition, I suspect that there are few hospitals in which a surgeon can rely on getting a comparatively complicated form filled in (including results of measurements of white cell count and serum concentrations of haemoglobin, creatinine, sodium, and potassium, as well as blood gas analyses) in 'under half an hour'.

I have already mentioned the multicentre trial by Cahill *et al.*[2] (of three methods of large bowel anastomosis) as being flawed by its lack of definitions. Among their conclusions was that: 'Adequacy of bowel preparation was reported as excellent or good in 84 per cent of cases, and as poor in only 3 per cent, with no difference between the groups.' To illustrate this they showed a table (*Table 4*) in which the numbers of patients receiving each type of bowel preparation (mechanical [unexplained], laxative, and enema) are given, as are the numbers receiving antibiotics [unspecified] and the route of administration (systemic or oral). What is not stated is how many patients received any particular combination or combinations of bowel preparation. It is possible from the table to deduce that 11 of 101 patients (10·9 per cent), six of 16 patients (38 per cent) and five of 85 patients (6 per cent) in the three groups, respectively, did not receive any antibiotics at all. It is, therefore, possible that the degree of bacterial contamination differed significantly among the groups, bringing into question an important aspect of their comparability that is not covered by *Table 1* (Patient details), but which could have had a profound influence on the results of the trial.

Again concerning operations on the large bowel, Horgan *et al.*[17] concluded that anal sphincter pressures were reduced after low anterior resection and that this reduction was caused by direct injury to the internal sphincter. In *Table 1* they give the preoperative measurement – we are not told if it is mean (standard deviation) or mean (standard error) – as 67(4), the measurement 10 days after operation as 51(4), and the measurement 6 months later as 53(5). In *Table 2*, however, the preanaesthetic value is given as 55(6); it is only in the text that it is disclosed that this value was obtained after premedication with a benzodiazepine. It does not differ significantly from the value 6 months after operation.

The last example of a Type III error is from Bird *et al.*[18] who suggested that: '...measurement of serum phospholipase A_2 activity may provide a simple test for the early identification of most patients with severe acute pancreatitis.' It may well do so, but the argument would have been more convincing had they compared the prognostic value of the test with the clinical outcome rather than with the results of another predictive test (Ranson) which, though it may be the best we have, is recognized as being less than perfect.

Inappropriate manipulation of numbers

I shall restrict myself to noting some of the more obvious statistical errors, as the topic has been reviewed by Murray[19] and I commend his paper. One of the most common ways in which authors manipulated numbers inappropriately was by using percentages in reporting their results. For example, Ball *et al.*[11] stated that: '88 per cent of patients over 70 who died had a preoperative blood urea above 15 mmol/l'. This sounds an enormous number, but study of the tables and methods shows that it means seven out of eight patients. Levy *et al.*[20] do give total numbers for their main groups, but give only percentages for morbidity and mortality within subgroups so that it is impossible to tell how many patients they are writing about in particular parts of the paper.

To take the use of percentages to its most ridiculous extreme, Kern *et al.*[21] referred to 3·5 per cent of 46 patients – this is 1·6 patients. Taberner *et al.*[22] wrote that of 14 patients in one group, 7·1 per cent were male, when what they meant was that there was one man. It is a convention of scientific writing that percentages should not be used at all if the total number is less than 25, they should be given in whole numbers if the total number is between 25 and 100, and only if the total number is greater than 100, may figures be given to one decimal place – and only one.

Percentages have their place, which is to compare one series with another. I fail to see the point of hiding raw data behind percentages, though authors may feel that publication of these calculations is expected of them. The author has to have the raw data to calculate them in the first place so he is making extra work for himself; this leads to the inevitable and sometimes correct conclusion that he is trying to conceal the small size of his sample. Canivet *et al.*[8] also used misleading percentages, it was not apparent until the data were 'tortured until they confessed'[23], that the percentage referred to a different number out of a different total on nearly every occasion.

Another common manipulation of numbers was the use of means and standard deviations (or standard errors) instead of medians and ranges (or interquartiles) for data that were not normally distributed. Murray[19] has already pointed this out, but his advice seems to have been unheeded. The standard deviation is a measure of the scatter of observations around the mean. If data are normally distributed, 95 per cent of the observations will lie within two standard deviations on either side of the mean; if the standard deviation is more than half the mean, therefore, the data are unlikely to be normally distributed. One example of the misuse of means and standard deviations is in the reporting of the length of hospital stay (which is never normally distributed); in several reports the figures seem to show that some patients left hospital before they were admitted.

Stansby and Greatorex[24] were clearly dealing with skewed distributions when they give the mean (s.d.) time to healing (in weeks) of pilonidal sinuses treated by excision and packing as 13·0 (7·5), range 2 to 37, compared with the time after phenol injection: 8·7 (5·5), range 1 to 23. They then report – despite such an enormous overlap – that this difference is highly significant ($P<0·001$) using Student's t test. One of the paradoxically reassuring things about this is that if they had not reported the range the overlap would not have been nearly so obvious.

There seems to be a widely held belief that a paper without P values is unpublishable. It is, however, obvious that some authors are ignorant of the purpose of tests of probability. For example, Pimpl *et al.*[25] felt it necessary to point out that 1 out of 100 was not significantly different from 0 out of 181, and disclosed that $P>0·1$.

All active drugs have unwanted side effects and the same may be said of computers. One of these is that they allow easy access to statistical tests that seem to give credence to even the most inadequate data. Fisher *et al.*[6] did a multivariate analysis of 11 variables in 65 patients, and Civalleri *et al.*[26] divided 35 patients first into three subgroups, and then each into a further five subgroups; they then applied statistical tests to the differences, and found that some of them were significant.

I am not sure that one should go as far as one eminent statistician and say that if a study needs sophisticated statistical analysis to prove a point it probably does not have much biological (or clinical) relevance, but I do urge that readers should use their common sense: *caveat emptor*.

Minor faults in presentation

Most of the minor faults in presentation can be attributed to carelessness. The prolific use of abbreviations, usually unnecessary, is not only thoughtless but bad manners. Many readers of *The British Journal of Surgery* have languages other than English as their mother tongues, and abbreviations confuse rather than help them. For example, CNS to one person means central nervous system, to another, coagulase negative staphylococcus. I came across the abbreviation CT used to mean 'cytotoxic chemotherapy' in a paper I was editing for another journal. Common sense tells us that long phrases like enzyme-linked immunosorbent assay (ELISA) may be abbreviated, but should always be spelled out the first time they are used. To abbreviate a term that is used only once or twice is unnecessary: fine needle aspiration biopsy was abbreviated to FNAB by Mitchell *et al.* in their Introduction, but mentioned only once more[27]. I await with interest the spelled out versions of M-AMSA[28] and FUdr[26].

Carelessness of expression may cause the reader to be confused about numbers in groups. Michaels *et al.*[29] studied: 'a total of 40 laser procedures … on 37 legs of 34 patients'. They reported that 13 procedures failed to recanalize the superficial femoral arteries; further on in the same paragraph, however, the number of failures was $5+2+3+4+2+2=18$. Authors should take great care to distinguish among totals, and make it absolutely clear to which they refer.

Naylor *et al.*[30] reported the causes of graft occlusion after aortofemoral bypass for peripheral ischaemia, and offended me by giving their results almost entirely in percentages. They also gave numbers in such a way that they could have referred either to subgroups of the total, or to separate groups in addition to the total. Presentation of the data in tables rather than in the text would have made them easier to follow.

Tables and figures

Every table and figure must have a title that requires no reference to the text for the reader to understand what it illustrates. If a table or a figure contains a lot of information a key may have to be included in a *brief* footnote, but long explanations should appear in the text. Better two simple tables than one complex one. Methods of interpreting scans, for example, should be described in the Patients and methods section, not in the figure legend[26].

Mistakes in diagrams included: the bars representing standard deviations above and below the mean were different lengths[31], the number of dots on a scattergram did not correspond to the number of patients given in the text[6], and the increments on the vertical axis of a graph differed by as much as 1 mm[29]. These mistakes show that the work was not checked adequately when it was returned from the medical art department.

Histograms were used quite often, and while they do have a place (when only an impression of the differences among proportions is important), in many cases, for example Winkler *et al.*[32], tabulation of the data would have been more informative as well as being easier to understand.

Matters of style

Most of the papers accepted by the journal were well written and contained none of the errors I have mentioned. I shall say little about the grammatical mistakes, convoluted sentences and tortuous prose found in a minority of papers. The first are usually corrected by the sub-editors and, concerning the last two, the extent to which style should be imposed by editors is a matter of opinion. Language should be '… a precision tool, conforming to simple rules and conveying meaning logically'[33].

On balance I come down in favour of the imposition of a fairly rigid style, principally because the aim of writing is not only to make yourself understood, but also to make certain that you are not misunderstood[34]. *The British Journal of Surgery* favours a more liberal approach to stylistic matters; nevertheless, nouns should not be used as verbs, verbs as nouns, or adjectives as adverbs. Superfluous words should be cut out. Purists may well be offended by such examples as Karanjia and Giddings[35] 'Histology of the biopsies' ('histological examination of biopsy specimens') and Mitchell *et al* [27] 'pancreatic mass lesion' ('pancreatic mass'). I sympathize with the 23 patients mentioned by Wilson *et al.*[36] who 'will soon achieve obliteration'.

I was pleased to see that only one abstract stated that 'The implications .. are discussed'[37]. Abstracts on the whole were informative, but there were still a few that were written in the active voice: abstracts should always be in the passive voice because they are often printed without alteration in abstracting journals. Several papers used the words 'approximate' and 'average' – surely too vague for serious scientific communications – and there was commonly confusion between 'prevalence' and 'incidence'. In a few papers there was a lack of consistency in terminology; to criticize this might be considered nit picking when the terms used were practically synonymous (for example, stricture and stenosis[6]), but carelessness in small matters undermines one's confidence in the authors' ability to deal correctly with large ones. Archy the cockroach could have been describing the philosophy of some medical writers when he wrote[38]: '*i never think at all when i write/nobody can do two things at the same time/and do them well*'.

This is a personal view, and I have no doubt that many will disagree with me. I do feel, however, that good research deserves to be presented well and that good presentation is as much a part of the research as the collection and analysis of the data. I have the impression that too many people submit manuscripts that have not been sufficiently edited, particularly by their senior authors whose help in the final stages of preparation of a manuscript may be perfunctory. This not only detracts from (and sometimes conceals) a valid message, but also reflects no credit on the writers or their critical faculties. We recognize good writing when we see it; let us also recognize that science has the right to be written well.

Intraoperative internal carotid artery restenosis detected by transcranial Doppler monitoring

D. M. Laman, A. Voorwinde*, G. Davies† and H. Van Duijn

*Departments of Clinical Neurophysiology, *Surgery and †Radiology, St. Lucas Hospital, Jan Tooropstraat 164, 1061 AE, Amsterdam, The Netherlands*

Correspondence to: Dr D. M. Laman

Several reports have described the monitoring of blood flow in the middle cerebral artery during carotid endarterectomy by means of transcranial Doppler sonography$^{1-5}$. The clinical applications of this method have still to be established$^{1-5}$. The value of monitoring by transcranial Doppler sonography is demonstrated in a patient who developed signs of restenosis during surgery.

Case report

A 65-year-old man presented with right-sided amaurosis fugax. Duplex Doppler ultrasound and transfemoral angiography demonstrated an occluded internal carotid artery on the left and 80–99 per cent stenosis on the right. Preoperative transcranial Doppler sonography (EME TC2-64 B®, EME GmbH Ueberlingen, FRG) findings are shown in *Table 1*. A right carotid endarterectomy with a venous patch was performed. By means of a fixed flat probe on the right temple, permitting a constant insonation angle, continuous transcranial Doppler sonographic monitoring of the right middle cerebral artery (*Figure 1*) mirrored the events described by Padayachee *et al.*[1]. Preclamp values at a depth of 50 mm were: mean blood flow velocity (MBFV) 52 cm/s, pulsatility index (PI) 0·53. Clamping of the right carotid artery caused an immediate drop in the MBFV in the right middle cerebral artery to 20–22 cm/s, indicating a residual flow of approximately 38 per cent PI was reduced to 0·28 (53 per cent of the preclamping value) A shunt was used because of low stump pressure (10–11 mmHg). The shunt caused an increase in the MBFV of the right middle cerebral artery to 32 cm/s (61 per cent of preclamping MBFV) and PI rose to 0·44 (83 per cent of the preclamping value). Immediately after endarterectomy and removal of the clamp, MBFV increased to 56–60 cm/s and PI to 0·72–0·76 (a 36 per cent increase compared with the preclamping value)

During wound closure these values remained unchanged. Gradual declines in both MBFV and PI were noted after 3 min while the patient was still under general anaesthesia with unchanged and stable blood pressure (80–90/40–50 mmHg, measured intra-arterially) The MBFV of the right middle cerebral artery shifted from 60 to 22 cm/s, and PI was lowered from 0·76 to 0·25, indicating a situation equivalent to the clamping procedure. A restenosis was suspected.

A second look at the operating site revealed no abnormalities. Good pulsations were felt in the entire length of the exposed internal carotid artery. Thereafter the flow pattern of the right middle cerebral artery showed some oscillations of MBFV and PI, ranging between clamping and shunt values and suggesting a restenosis of fluctuating severity. Intra-arterial mean blood pressure measurements across the operating site showed no changes. A peroperative carotid angiogram showed poor filling of both the external and internal carotid arteries, indicating obstruction at the site of surgery.

The bifurcation was re-explored. Clamping and shunt procedures caused the same transcranial Doppler sonography patterns as before (*Figure 1*). Inspection of the reopened carotid artery showed a dorsally situated intimal flap at the distal end of the arteriotomy. This was sutured and a new venous patch was implanted.

After release of the clamp, MBFV in the right middle cerebral artery was 76 cm/s and PI was 1·00. Postoperative measurements showed the same values, and the patient regained consciousness without neurological sequelae. The following day transcranial Doppler

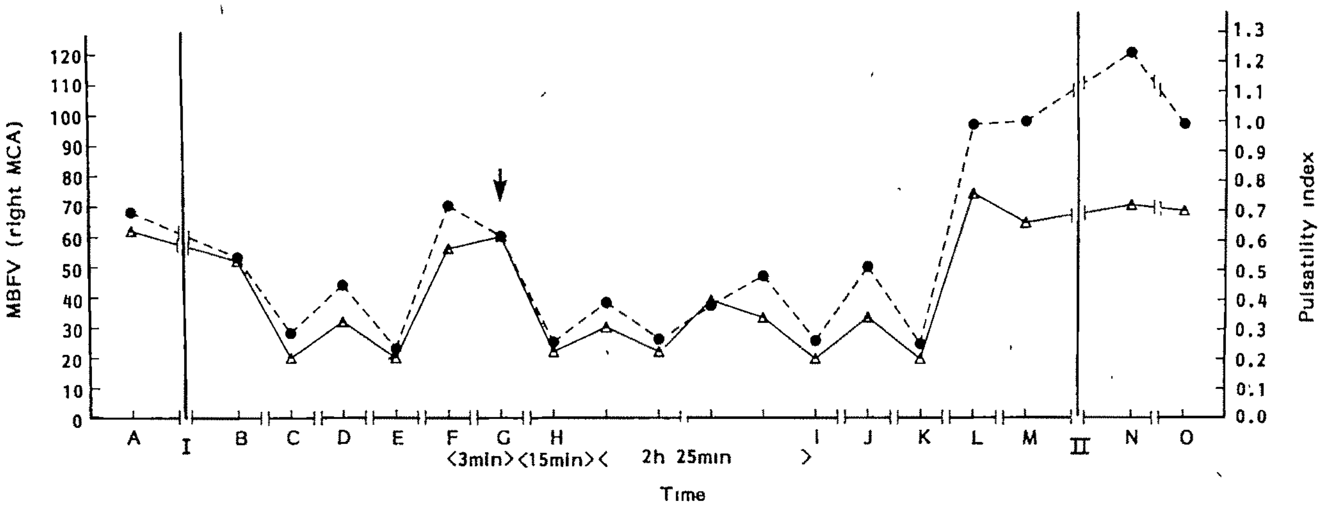

Figure 1 *Transcranial Doppler sonography. preoperative, intraoperative and postoperative parameters from the right middle cerebral artery (MCA), depth setting 50 mm.* △, *Representative values of the mean blood flow velocity (MBFV),* ●, *representative values of the pulsatility index Related events are shown on the x axis as follows: A, preoperative values,* I–II, *right carotid endarterectomy (continuous monitoring B–L), B, under anaesthesia, C and E, clamp* I *on, D, shunt* I, *F, clamp* I *off, G, start gradual decline (arrow), H, situation equivalent to clamp procedure; H–I, oscillations, I and K, clamp* II *on; J, shunt* II; *L, clamp* II *off; M, recovery room; N, day 1 after operation; O: day 40 after operation. Time intervals are shown between brackets*

sonography showed a normal flow pattern in the right middle cerebral artery with a pulsatility transmission index (PTI) of 1·05 (reference· basilar artery, normal >0.92) (Reference 6), indicating a restored and unimpeded flow in the right internal carotid artery (see *Table 1*).

Forty days after carotid endarterectomy transcranial Doppler sonography recording was unchanged (*Figure 1, Table 1*) with a normal PTI (0.95) of the right middle cerebral artery (reference. basilar artery). Duplex scanning of the right bifurcation showed no signs of restenosis.

Discussion

Non-invasive basal cerebral artery blood flow velocity measurement by transcranial Doppler sonography has been available since 1982[7]. This type of monitoring in carotid endarterectomy has been used to decide whether to apply a shunt or not[4], a procedure known to have certain hazards[8]. The number of early restenoses after carotid endarterectomy is unknown[9]. The restenosis in our patient caused oscillating changes in MBFV and PI of the ipsilateral middle cerebral artery compatible with a fluctuating haemodynamically significant lesion, presumably due to an intimal flap. Early intraoperative restenosis of the carotid artery detected by transcranial Doppler sonography monitoring of the middle cerebral artery during endarterectomy has not been reported before This type of monitoring may prove to be useful when intraoperative angiography or duplex scanning are not available routinely.

Congenital diaphragmatic hernia

S. Nour, E. Wing*, N. Pereira and A. E. MacKinnon

*The Children's Hospital, Sheffield, and *Scunthorpe General Hospital, Scunthorpe, UK*

Correspondence to: Mr A. E. MacKinnon, The Children's Hospital, Western Bank, Sheffield S10 2TH, UK

Congenital diaphragmatic hernia most commonly presents as an acute neonatal surgical emergency on the first day of life and has a mortality rate approaching 50 per cent[1]. Babies who present after the first 24 h of life have a much better prognosis. In the majority of cases the diagnosis is suspected on clinical grounds and is confirmed by the classical radiological features[2]. Our patient presented with an unusual history, and although the correct diagnosis was suspected on the first chest radiograph, subsequent films, with complete disappearance of the herniated gut, led to a delay in confirmation of the diagnosis.

Case report

A male infant was born by normal delivery on 24 June 1988, at 36 weeks' gestation. Apgar scores were 8 and 10 at 1 and 5 min respectively. He had transient tachypnoea of the newborn but made a smooth recovery and went home 96 h later. He re-presented on 3 and 11 August 1988 with a history of constipation and bleeding *per rectum*. An anal fissure was diagnosed and treated conservatively. He presented again on 14 August with acute respiratory failure. Before admission he had been straining to pass stool, became red and was shaking, then went blue and flaccid for 1 min. On arrival at hospital he was still cyanosed and irritable, with tachypnoea and tachycardia. His abdomen was tender in the right hypochondrium, and on chest examination there were bilateral crepitations. Laboratory investigations showed a mild metabolic acidosis and a haemoglobin of 8 g/dl. He was resuscitated with blood and plasma infusion. A chest radiograph (*Figure 1*) showed almost complete opacity of the left hemithorax, right upper lobe pneumonia, and mediastinal shift to the right. A provisional diagnosis of left congenital diaphragmatic hernia was made, an endotracheal tube was passed, and the patient was referred to the Children's Hospital in Sheffield.

On arrival, repeat chest radiograph revealed that the endotracheal tube had slipped into the right main bronchus (*Figure 2*). Following neuromuscular blockade and reintubation, a chest radiograph showed complete aeration of the left lung (*Figure 3*) and the patient made a dramatic improvement, but the apex beat did not return to a normal position. He was ventilated electively from 14 until 18 August, and then extubated. He remained well until 18 h later when he became tachypnoeic and the transcutaneous P_{O_2} dropped from 14 kPa to 8 kPa. A repeat chest radiograph showed the classical features of a left congenital diaphragmatic hernia (*Figure 4*).

At laparotomy the intestine was found to be normally rotated and in the abdominal cavity. There was a small left posterolateral diaphragmatic defect 5 cm in diameter with the spleen trapped in the pleural cavity. We had to extend the defect to deliver the spleen into the abdomen before repair. The baby made an excellent postoperative recovery.

Discussion

This infant presented an unusual and interesting picture with potentially serious consequences. The referring paediatrician established the correct diagnosis. Confusion arose from the initial radiograph taken after transfer showing the misplaced endotracheal tube and complete absence of gas in the left hemithorax. The immediate clinical and radiological improvement following reintubation led us to conclude that there had been solely an obstructive airway problem. Insufficient attention was paid to the evidence of persisting mediastinal shift, and the possibility of a diaphragmatic hernia was dismissed.

We consider that the spleen acted as a plug in the diaphragmatic defect, a situation previously reported by Rø et al.[3]. While there was a small differential pressure between abdomen and chest, no herniation of gut could occur. However, the straining due to constipation may easily have so increased the intra-abdominal pressure that the spleen was displaced and herniation of gut occurred. When neuromuscular paralysis and full ventilation were established, the positive intrathoracic pressure forced the gut back into the abdomen, only to reherniate after extubation. We suggest that the gut was not forced back into the abdomen at the initial phase of ventilation because at that time the spleen blocked the defect in the opposite direction to its previous plugging effect. This unusual clinical picture has not been previously described.

^{99m}Tc-labelled HIDA scintigraphy in assessment of bile leakage after removal of T tube from the common bile duct

N. Ryttov, L. Rasmussen, S. A. Pedersen and E. Öster-Jörgensen*

*Department of Surgical Gastroenterology and * Department of Radiotherapeutics, Division of Diagnostic Nuclear Medicine, Odense University Hospital, DK-5000 Odense C, Denmark*

Correspondence to: Dr S. A. Pedersen

Bile peritonitis occurring after removal of a T tube from the common bile duct is generally regarded as a rare, but potentially fatal, complication[1,2]. This study investigates whether the information obtained by scintigraphy with ^{99m}Tc-labelled Sn-2,6-di-ethylacetanilidoiminodiacetic (^{99m}Tc-labelled HIDA) can contribute to the selection of patients requiring reoperation because of bile peritonitis.

Patients and methods

Ten patients, six women and four men with gallstone disease, median age 69 years, all of whom had a normal hepatic function and normal T tube cholangiography, had scintigraphy 24 h after T tube removal, as previously reported[3,4]. Recording of polaroid pictures from an oscilloscope was performed and each image covered 4 min.

Results

The T tubes were removed after a median of 8 days (range 8–10 days).

The patients fell into three groups. The first group comprised six patients who demonstrated normal findings: all had an uneventful course. In the second group of two patients nearly all the activity was in the duodenum. In one patient who had no symptoms, some activity was present in the gallbladder bed. The second patient demonstrated a more widespread accumulation of activity in the subhepatic area and he had clinical signs of bile periotonitis; he was treated conservatively. This patient was discharged, but readmitted 13 days after removal of the T tube to be treated surgically for a symptomatic subhepatic accumulation of bile. In the third group (two patients), all the activity extravasated into the peritoneal cavity (*Figure 1*). Both patients developed bile peritonitis requiring reoperation and reinsertion of a T tube. These operations were performed 29 h and 79 h after removal of the T tube.

Discussion

After T tube removal from the common bile duct, where symptoms suggestive of a major bile leak arise, diagnosis by X-ray examination is uninformative[5]. Ultrasonography and computed tomography are clinically accurate techniques. However, these techniques are unable to determine if a fluid collection is due to bile or blood or if bile is passing into the duodenum.

Based on the reservations mentioned above we evaluated ^{99m}Tc-labelled HIDA scintigraphy. In normals this examination clearly delineates the liver and the extrahepatic biliary tract. Activity in the duodenum is usually seen within 1 h and earlier in a subject with a normal hepatic function and a previous cholecystectomy[6]. Activity outside the liver, biliary tract, and intestine is easily identified. The findings in this study demonstrate that there is a relationship between the scintigraphic findings and the clinical course. As expected, the most common finding was activity within the biliary tract and duodenum and all these patients had a normal clinical course. Among the two patients with subhepatic accumulation of activity as well as intestinal activity, the one with the most pronounced leakage was readmitted and treated for a subhepatic accumulation of bile. The two patients who had no intestinal activity both developed clinical signs of peritonitis and were operated on. Scintigraphy was performed 24 h after removal of the T tube in this study, but it is probable that the same information can be obtained if the investigation is performed a few hours after removal of the T tube. If the pain after a T tube removal persists we recommend that ^{99m}Tc-labelled HIDA scintigraphy is performed. Immediate surgery is advocated when no activity passes to the duodenum. If the scintigraphy demonstrates activity in the intestine as well as extravasation of activity into the peritoneal cavity then the patient should be monitored closely and the indication for surgery based on the subsequent clinical course.

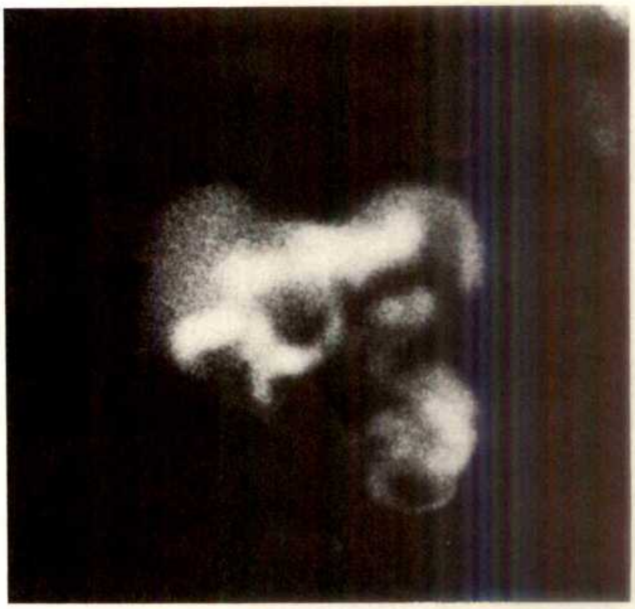

Figure 1 *^{99m}Tc-labelled HIDA scintigraphy demonstrating extravasation of all activity to the peritoneal cavity*

Salvage of an exposed arterial prosthesis by tissue expansion

I. T. H. Foo and C. M. Ward

Department of Plastic and Reconstructive Surgery, Charing Cross and West Middlesex University Hospitals, London, UK

Correspondence to: Mr I. T. H. Foo, Plastic Surgery and Burns Research Unit, University of Bradford, Bradford West Yorkshire BD7 1DP, UK

Tissue expansion is well established in reconstructive procedures. The first case of controlled tissue expansion was performed by Neuman in 1957[1] by means of an inflatable device placed subcutaneously in the reconstruction of an ear. This technique has since been popularized in breast reconstruction[2–4], in the head and neck region[5] and in the upper and lower extremities. However, the principle is not widely applied in the general surgical field. We report a case in which a groin defect with an exposed arterial prosthesis was covered with the help of tissue expansion when none of the normally available local flaps could be used.

Case report

A 58-year-old patient with arteriopathy was referred with an exposed Dacron® (du Pont) prosthesis. In the past he had had several operations to improve his intermittent claudication including, in 1974, an aortobifemoral graft. This operation had improved his symptoms until 1983 when he developed claudication in the right leg following occlusion of the right limb of the graft. A right axillofemoral prosthesis temporarily improved his symptoms until 1986 when a right below-knee amputation became necessary. In July 1987, the patient had a right-to-left femorofemoral cross-over graft to overcome an occlusion of the left limb of his bifurcated graft. The wound in his left groin failed to heal resulting in an exposed arterial prosthesis. Several attempts to close the wound were unsuccessful.

Previous abdominal incisions and the state of his arterial tree prevented the use of the usual flaps available for achieving cover of a groin defect. A tissue expander was, therefore, placed in the anterolateral aspect of the thigh in a suprafascial pocket through a new incision. This was rapidly expanded to a volume of 450 ml in 2 weeks, the interval of expansion being from 24 to 48 h (*Figure 1*). When enough skin expansion had been achieved, the graft was mobilized from its bed and the wound was debrided. The sartorius muscle was detached from its origin and transposed over the graft to provide insulation and protection in the event of wound breakdown. Finally, the expanded skin was advanced to permit tension-free closure.

The arterial prosthesis, which was patent at the end of the procedure, failed 48 h later. Re-exploration revealed a thrombus at the origin of the cross-over graft and in the right limb of the bifurcated graft. Despite several attempts to re-establish flow, the patient required a below-knee amputation and was subsequently discharged from hospital.

Discussion

Under normal circumstances, the following muscle or myocutaneous flaps could have been transposed to cover a groin defect. The rectus abdominis muscle, based on the inferior epigastric artery, is normally ideal but this vessel had been transected in the course of previous surgery. The integrity of the medial and lateral circumflex arteries could also not be relied upon, thereby making the use of the gracilis, tensor fasciae latae, rectus femoris and vastus lateralis muscles unattractive. However, on elevating the sartorius muscle in the present case, there was gratifying bleeding from its cut surface and hence this muscle was used to insulate the prosthesis.

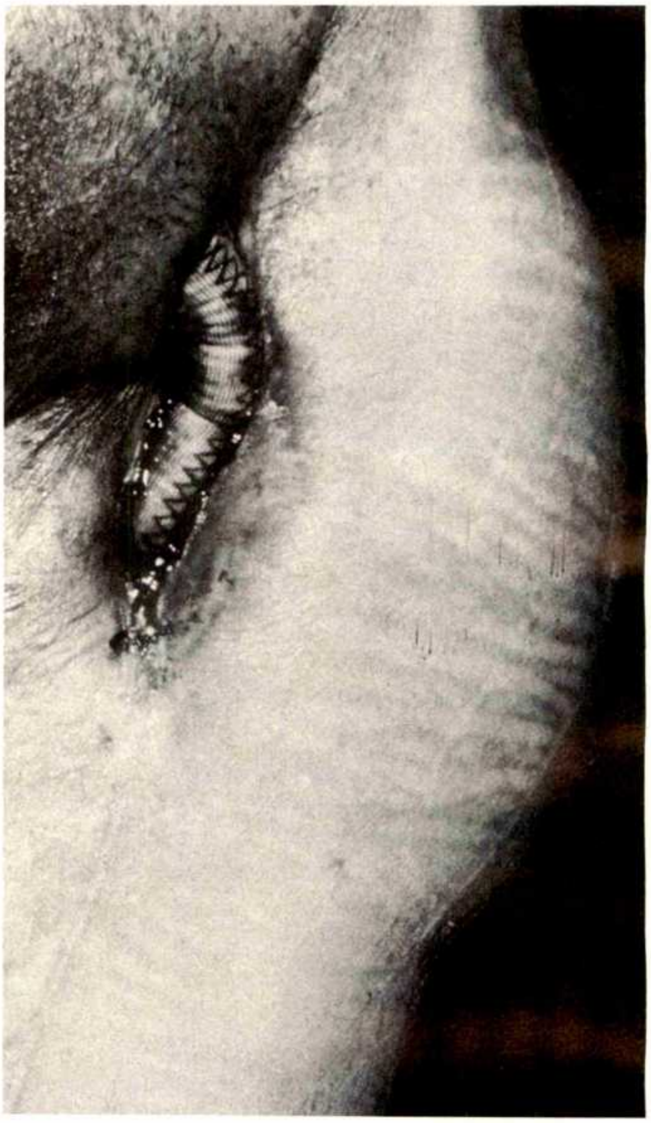

Figure 1 *Left groin: exposed arterial prosthesis and neighbouring dome of expanded skin*

In this case, a tissue expander provided 'extra' skin[6–8] and enhanced the viability of the flap ('delay phenomenon'). The mechanism of 'delay' is an increase in flap vascularity by vessel reorientation and hypertrophy, with metabolic adaption of the flap in response to surgical interruption of a portion of its blood supply[9,10].

We doubt that closure of the wound with an expanded skin flap contributed significantly to eventual graft failure. We feel that in the present case, where there was no alternative, tissue expansion was a good option, allowing closure of the groin wound with neighbouring skin without the added problem of donor site morbidity.

Délorme operation for prolapsed colostomy

A. M. Abulafi, I. W. Sherman and R. V. Fiddian

Department of Surgery, Luton and Dunstable Hospital, Lewsey Road, Luton LU4 0DZ, UK
Correspondence to: Mr A. M. Abulafi, Department of Surgery, The London Hospital, Whitechapel, London E1 1BB, UK

Stomal prolapse is a complication more frequently found in loop than end colostomies. It can be large enough to make appliance fitting difficult and to make an unsightly bulge.

The principles of Délorme's procedure originally described for rectal prolapse were used in two patients with colostomy prolapse with satisfactory results.

Surgical technique[1]

Under general or local anaesthesia the prolapse is fully extended using Babcock forceps and sufficient 1:400000 adrenaline solution is injected submucosally to elevate all the exposed mucosa (*Figure 1*). This facilitates dissection in that plane and greatly reduces bleeding. A circumferential mucosal incision is made 10–15 mm from the mucocutaneous junction (*Figure 2*). The mucosa is then dissected from the muscularis to the apex of the prolapse. Six to eight plicating sutures of an absorbable material (our preference is for No. 1 polydioxone, Ethicon Ltd., Edinburgh, UK) are inserted in the muscular wall of the colostomy between the mucosal cut edges at the mucocutaneous junction and the apex (*Figure 3*). The sutures are then tied forming a doughnut-like mass which is reduced gently. The mucosal sleeve is then divided and the cut ends of the mucosa are sutured together with 3/0 catgut (*Figure 4*).

Two patients with prolapsed colostomies were successfully treated using this technique. One patient was a 64-year-old woman with a 15 cm long prolapsed permanent left iliac end colostomy. The other was an 84-year-old woman with a 30 cm prolapse of both limbs of a permanent right transverse loop colostomy. The former was treated in February 1985 and the latter in February 1988. Both patients were satisfied with the result of the operation and to date both patients have less than 2·5 cm of prominent mucosa.

Discussion

Colostomy prolapse is a complication with an overall incidence of 2·4–26 per cent[2]. Various methods have been advocated to treat this condition. In terminal colostomy the traditional approach is to excise and reconstruct the colostomy. A simpler procedure is to amputate the redundant bowel but this may be complicated by gangrene of the mucosal cuff and damage to an associated enterocoele[3]. Goligher mobilized the prolapsed colostomy at the mucocutaneous junction dividing it at a point 12–18 mm beyond the anterior abdominal skin and then sutured the cut end of bowel to the skin[4]. Recently Corry described a simple method using a subcutaneous pericolostomy suture

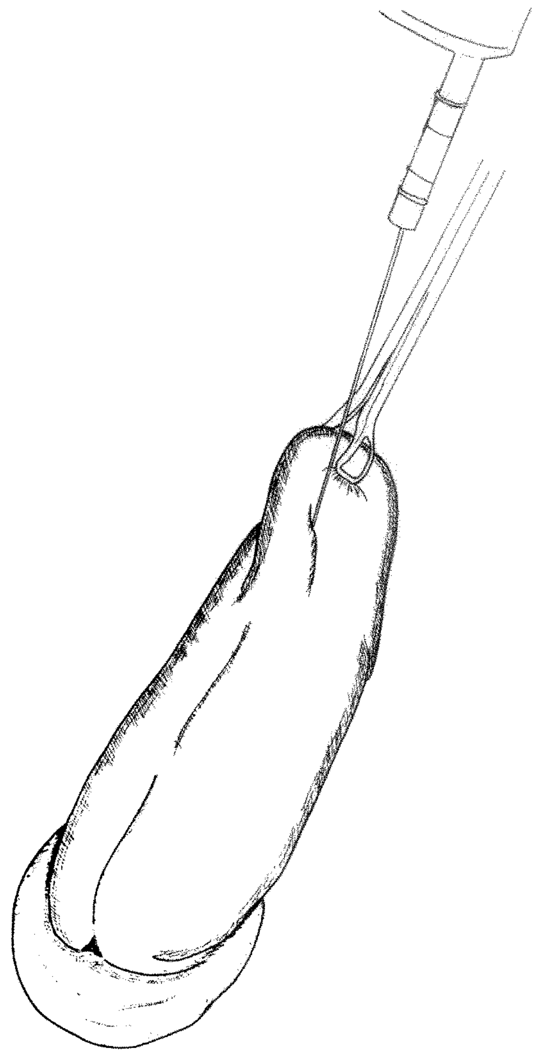

Figure 1 *The submucosal layer is infiltrated with a solution of saline and adrenaline to facilitate the mucosal dissection*

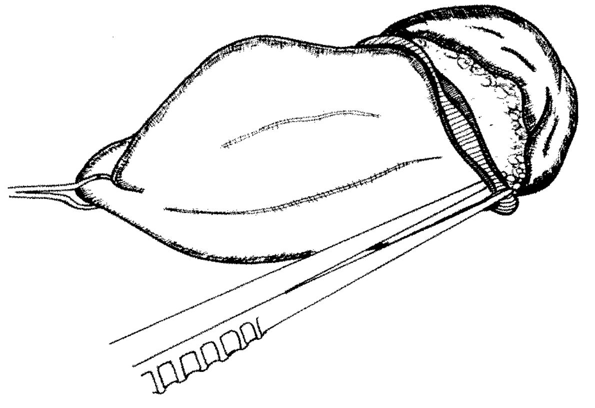

Figure 2 *An incision is made circumferentially around the mucosa 10–15 mm from the mucocutaneous junction, and the mucosa dissected proximally*

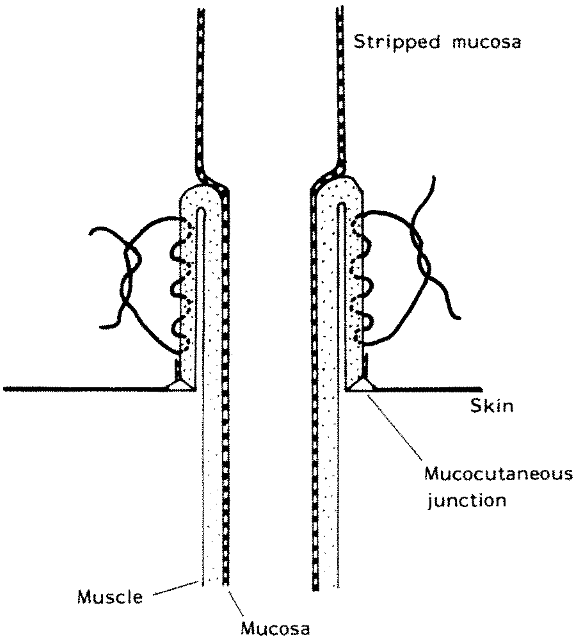

Figure 3 *When the mucosa has been stripped away from the muscle, 6–8 plicating sutures are inserted*

applying the same principle as that of the Thiersch operation for rectal prolapse[5].

Loop colostomy is usually temporary and prolapse is best treated by closure of the colostomy when the circumstances for which the loop was raised are passed. In the rare situation where the stoma is permanent, the loop can be divided fashioning a single barrelled proximal stoma and closing the distal end which is returned into the abdomen.

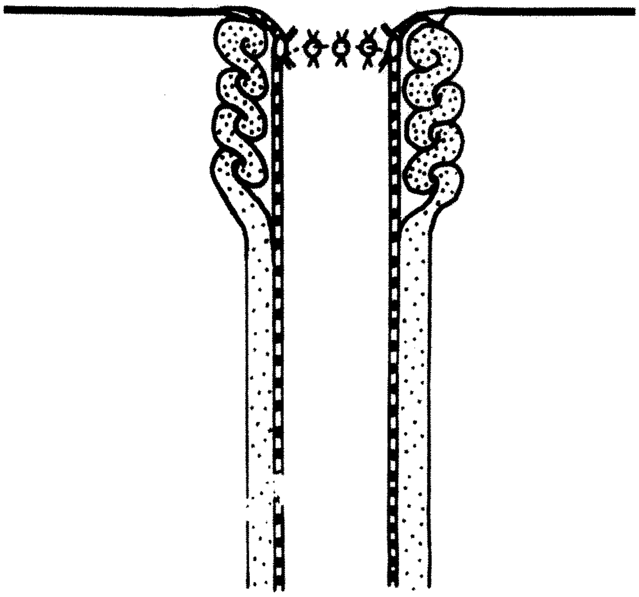

Figure 4 *After reduction of the hernia, the mucosal edges are sutured with interrupted stitches*

Délorme's repair is a simple and effective means of treating prolapsed colostomy, as in our two cases: one of these has been followed up for 3 years, with no significant recurrence. The mucosal protrusion of less than 2·5 cm in both patients did not affect appliance fitting and both were unaware of its presence. We feel it should be considered in elderly and unfit patients not suitable for major surgery. Any late recurrence could be treated with a further Délorme's procedure.

Prospective comparison of preoperative imaging and intraoperative ultrasonography in the detection of liver tumors

Maureen P. Clarke, MD, Robert A. Kane, MD, Glenn Steele, Jr., MD,
Edna S. Hamilton, MD, Thanjavur S. Ravikumar, MD, Gary Onik, MD, *and*
Melvin E. Clouse, MD, *Boston, Mass.*

*A prospective evaluation of the accuracy of preoperative computed tomography (CT), ultrasonography (US), and angiography was performed in 54 patients undergoing resection of hepatic neoplasms. The results were compared with surgical findings and intraoperative ultrasonography (IOUS). A total of 167 lesions was seen by means of IOUS, of which preoperative US enabled detection of 127 (76%). In 48 patients CT allowed detection of 91 of 150 lesions (61%), and in 35 patients angiography showed 56 of 107 lesions (52%). When the detection rate is analyzed according to hepatic segment, the greater overall accuracy of preoperative US may be attributed to a markedly better detection rate in lateral segment of the left lobe of the liver. Lesion size also represented a factor, with preoperative US allowing detection of a greater number of small (less than 2 cm) lesions compared with CT. In patients studied with both CT and US, the combined lesion-detection rate increased to 81% in the right lobe and 76% in the left lobe. Because of this we recommend that preoperative assessment include both CT and US evaluation of the liver. IOUS showed 25% to 35% additional lesions compared with preoperative US and CT. More importantly, 40% of the lesions demonstrated by IOUS were neither visible nor palpable at surgery. We recommend that IOUS be considered in all patients in whom resection of hepatic neoplasm is planned. (*SURGERY *1989;106:849-55.)*

From the Departments of Radiology and Surgery, New England Deaconess Hospital, Boston, Mass.

SEVERAL PREVIOUS STUDIES have compared the relative accuracy of computed tomography (CT), ultrasonography (US), and angiography in detecting hepatic tumors.[1-8] Earlier comparative studies have indicated that CT is the most accurate modality. However, there is recent evidence to suggest that US is more sensitive in the detection of small tumors.[9] This study is a prospective series comparing preoperative CT, US, and angiography to surgical findings and intraoperative ultrasonography (IOUS) of the liver. With this approach, a better assessment of the accuracy of these preoperative imaging modalities may be obtained, as well as an evaluation of the utility of IOUS.

MATERIAL AND METHODS

Fifty-four patients undergoing planned hepatic resection with concomitant IOUS during March 1985 through May 1987 were included. The majority of these patients were referred for surgical treatment of metastatic colon carcinoma. A smaller number of patients with other metastatic cancers to the liver, as well as primary hepatic tumors, were also studied. These included four hepatocellular carcinomas, one cholangiocarcinoma, and one metastatic glucagonoma. The patients were examined preoperatively with a combination of CT, US, and angiography. The size, number, and segmental location of lesions were recorded and compared with the findings of IOUS, as well as surgical palpation and inspection. Also noted were other findings, such as vascular invasion and extrahepatic disease.

Preoperative ultrasonograms were taken with an annular array (Technicare, Lewiston, Pa.) or a

mechanical sector scanner (DRF400; Diasonics, Inc., Milpitas, Calif.), with use of both 3.5 and 5 mHz transducers. The liver was examined with the patient in supine and left lateral decubitus positions. Transverse and sagittal views were obtained using both subcostal and careful intercostal scanning. When needed, the examination was expanded to include upright views for better visualization of the dome of the liver and intercostal scanning with 5 mHz transducer to image the periphery of liver. The routine study also included evaluation of pancreas, kidneys, spleen, celiac, periportal and mesenteric lymph nodes, and retroperitoneum. Preoperative CT evaluation at our institution was performed with a scanner (GE8800; General Electric Co., Milwaukee, Wis.), with use of 1 cm contiguous slices after the administration of intravenous contrast material by multiple bolus injections. The initial bolus consisted of 50 ml of Renograffin 60, followed by two 25 ml boluses. Sequential scans were obtained after each bolus. For some patients, CT scans from outside referring hospitals were included in the study. These were from a variety of modern scanners using contrast-enhanced technique. Noncontrast CT scans were only obtained in two patients with a history of contrast reaction. Angiographic evaluation was performed via selective catheterization of celiac, hepatic, and superior mesenteric arteries.

The results of preoperative imaging were compared with IOUS and surgical findings. The IOUS examination was performed by the radiologist after surgical mobilization of the liver. Direct scanning of the liver was accomplished with both 5 mHz and 7.5 mHz intraoperative probes (Aloka 330; Colormetrics Medical Systems, Inc., Wallingford, Conn.). The IOUS examination included demonstration of hepatic vein confluence, inferior vena cava, and the main, right and left portal veins. Lesions known from preoperative imaging were identified and their relationship to adjacent hepatic and portal veins established. The entire liver was then systematically scanned with both 5 mHz and 7.5 mHz probes. Additional lesions were recorded and localized according to hepatic segment. Other findings such as vascular invasion were also noted. The findings were correlated to surgical palpation, as well as visual inspection of surface lesions.

RESULTS

The number of lesions detected by surgical findings and IOUS were compared with the preoperative findings and categorized according to segmental location. The total accuracy of each modality was recorded, as well as the segmental and lobar accuracy distribution. In 54 patients 167 lesions were detected with IOUS, of which preoperative US showed 127 (total accuracy of 76%). In 48 patients preoperative CT showed 91 of 150 lesions seen at IOUS (total accuracy of 60.6%). In 35 patients angiography showed 56 of 105 lesions seen at IOUS (total accuracy of 52.3%).

The surprisingly greater detection rate of preoperative US versus CT scanning is explained when the accuracy is broken down according to hepatic segments (Table I). With preoperative US the accuracy of detection of lesions by segment and lobe are similar (right lobe, 77.5%, versus left lobe, 74.5%). However, the preoperative CT scan shows a significant discrepancy in detection in right and left lobe lesions compared with IOUS (right lobe, 74.4%, versus left lobe, 36.3%). This difference is most pronounced in the detection of lesions in the lateral segment of the left lobe of the liver where preoperative US showed 77.5% of the lesions versus 28.9% by CT scan. This is probably related to decreased CT resolution of left lateral segment lesions due to image degradation by streak artifacts from the stomach and by cardiac motion (Fig. 1). In patients studies preoperatively with both CT and US, the combined detection rate increased to 80.8% in the right lobe and 76.3% in the left lobe. In the fewer number of patients studied with both CT and angiography, the accuracy in the right

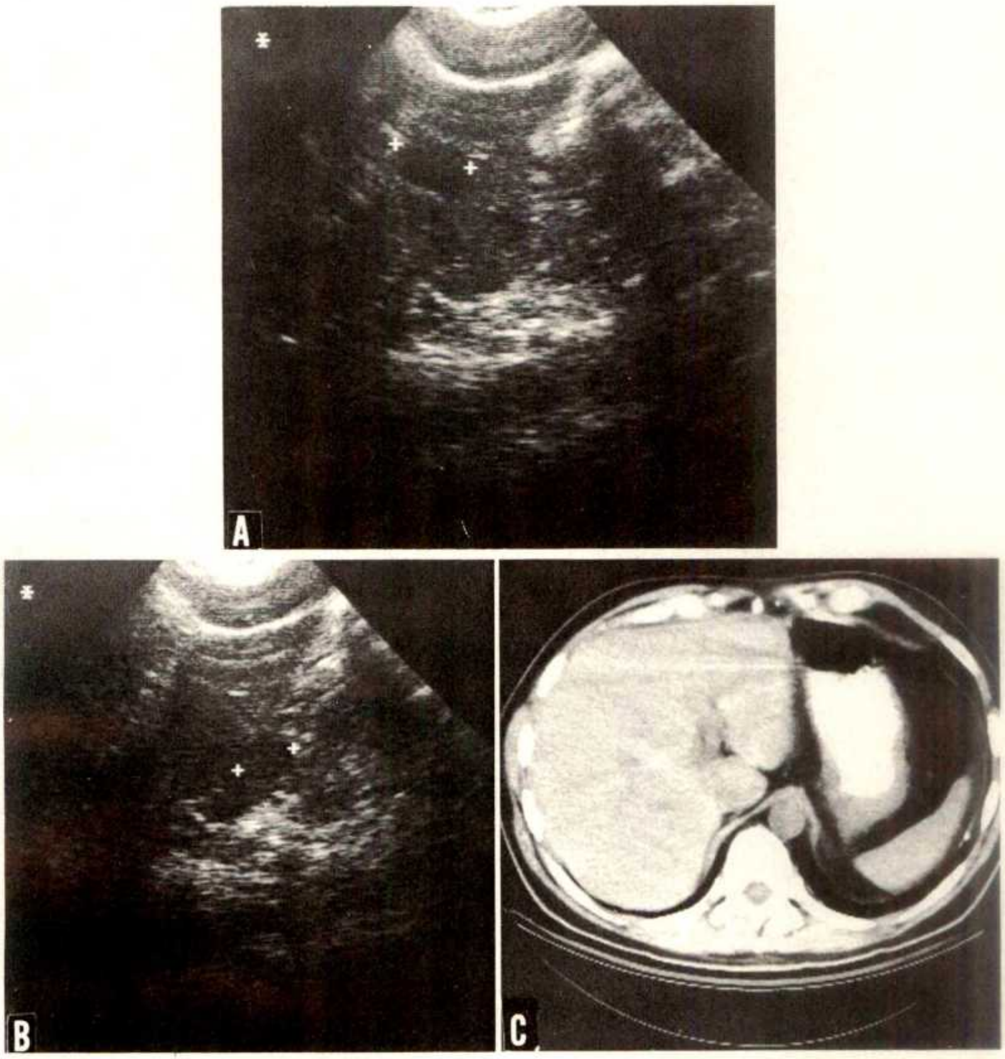

Fig. 1. **A** and **B**, Preoperative US, sagittal views, lateral segment of left lobe shows two hypoechoic masses. **C**, CT scan lateral segment of left lobe, same patient. Above lesions not identified due to streak artifact from stomach.

lobe was similar (78.4%). In the left lobe, however, the combined accuracy was no greater than that of CT alone.

Angiography detected 65.7% of right-lobe lesions and 23.5% of left-lobe lesions. This was attributed to both small lesion size and the hypovascular nature of colonic metastases. Of the 35 angiography patients, six had noncolon primary tumors. Although this represents a small number, the accuracy of detection of lesions in this group increased to 75% in the right lobe and 50% in the left lobe. Tumors missed in this group were small hypovascular lesions.

The detection rate was also influenced by the size of the lesion. Lesions more than 3 cm in diameter were generally imaged by all modalities. Most of the lesions seen by preoperative US and missed by CT scan were small, measuring 1 to 2 cm. In several cases IOUS showed lesions less than 1 cm in diameter that were not visible preoperatively by any modality (Fig. 2). Forty percent of the lesions seen with IOUS were neither visible nor palpable in surgery.

In the case illustrated in Fig. 2, C, IOUS showed multiple small lesions in the right lobe in addition to the two lesions in the left lobe, seen with preoperative imaging. The planned left hepatic lobectomy was not performed because of the bilobar involvement. The

Fig. 2. Superior resolution of IOUS shows multiple echogenic lesions measuring 5 mm and less in diameter, not seen preoperatively.

right lobe lesions were followed up and found to increase in size. A biopsy specimen was positive for tumor.

Of the 54 patients, six had tumors deemed unresectable at surgical exploration because of extent of hepatic disease or evidence of extrahepatic spread of tumor. IOUS showed the lesions of an additional five patients to be unresectable on the basis of extent of tumor involvement of both lobes, which was not evident preoperatively. In another 17 patients the findings of IOUS altered the surgical plan. These findings included localization and discovery of new lesions and demonstration of extent of vascular invasion by tumor. For example, the preoperative plan of lobectomy could be altered to an extended lobectomy or trisegmentectomy to include new lesions discovered with IOUS. In addition, tumors amenable to wedge resection could be accurately localized. In some cases, IOUS-monitored cryosurgery of lesions was performed in conjunction with resection.[10] Thus the findings of IOUS changed the surgical plan in 32% of the patients studied.

DISCUSSION

IOUS is currently performed in many institutions as an adjunct to hepatic resection. The information provided by this procedure has influenced surgical planning and encouraged a reevaluation of preoperative diagnostic imaging. The greater detection rate of preoperative US versus CT demonstrated in our study is in contradistinction to many reports. However, the accuracy of

IOUS versus preoperative imaging in both primary and metastatic neoplasms has been compared in recent literature (Table II). One study (Gozzetti et al., 1986), demonstrated a greater accuracy of preoperative US (80%) versus CT scan (74%), in agreement with our findings.[11] In a study restricted to hepatocellular carcinomas of less than 5 cm in diameter (Sheu et al., 1985), the accuracy of preoperative US again surpassed CT scanning.[12] Castaing et al.[13] reported an equal accuracy of preoperative CT and ultrasound. Another (Gunven et al., 1985) agrees with the previusly reported greater accuracy of preoperative CT compared with US and angiography.[14] As in older studies, the preoperative US examinations in this case were performed with static gray scale scanners rather than current real-time technology. This most likely contributed to the lower accuracy of preoperative US since complete assessment of liver parenchyma requires the flexibility of real-time US, especially for upright and decubitus subcostal and intercostal scanning.

Analysis of the detection rate of each modality by hepatic segments provides insight into the cause of the discrepancy. CT has the lowest detection rate in the left lobe of the liver, particularly the lateral segment. Images of this area are frequently degraded by cardiac motion and by streak artifacts related to the stomach or transverse colon. CT is slightly more accurate in detecting lesions in the dome of the liver and lateral costal margin, areas which can be difficult to fully assess by US (Fig. 3). Angiography is also limited in the left lobe, particularly with small or hypovascular lesions, because of the overlapping spinal column.

The size of lesions also represents a factor in determining accuracy of detection. Small lesions measuring 1 to 2 cm in diameter are best seen with US. Because of slice thickness, volume averaging, and respiratory motion, these lesions could be partially imaged or missed by CT. All preoperative imaging modalities missed the presence of small surface lesions that were visible only at surgery.

In one case of hepatocellular carcinoma, a diffusely infiltrating lesion was missed prospectively with a contrast and noncontrast CT scan. US showed tumor present in both lobes of the liver, as well as invasion of the portal vein (Fig. 4). This suggests that US may have an advantage in imaging infiltrating neoplasms by the detection of heterogeneous liver texture and architectural abnormalities that may not present as focal lesions on CT scan. Although both US and angiography show vascular invasion, US can show tumor within veins that are not opacified at angiography.[15] However, only with angiography can one identify arteriovenous shunting. CT is considered less accurate in showing tumor invasion of the venous structures.[16] In our series, there were two cases of venous invasion—one into the portal vein and the other into the inferior vena cava. Invasion of the inferior vena cava was seen with both CT and US, whereas the portal vein invasion was seen only with US.

Of interest is the incidental finding by preoperative US of three renal masses, each measuring approximately 2 cm in diameter. These consisted of one angiomyolipoma and two renal cell carcinomas. One of the renal cell carcinomas was missed with a noncontrast CT scan. The other renal cell carcinoma was an exophytic lesion, extending from the lower pole of the left kidney, and was not included on the contrast CT scan of the liver.

The use of IOUS has become increasingly important in hepatic resection for depiction of liver anatomy and localization of tumors to specific lobes and segments. It has facilitated the detection and biopsy of small lesions and demonstrated the relationship of tumors to major intrahepatic vessels. The information provided by IOUS

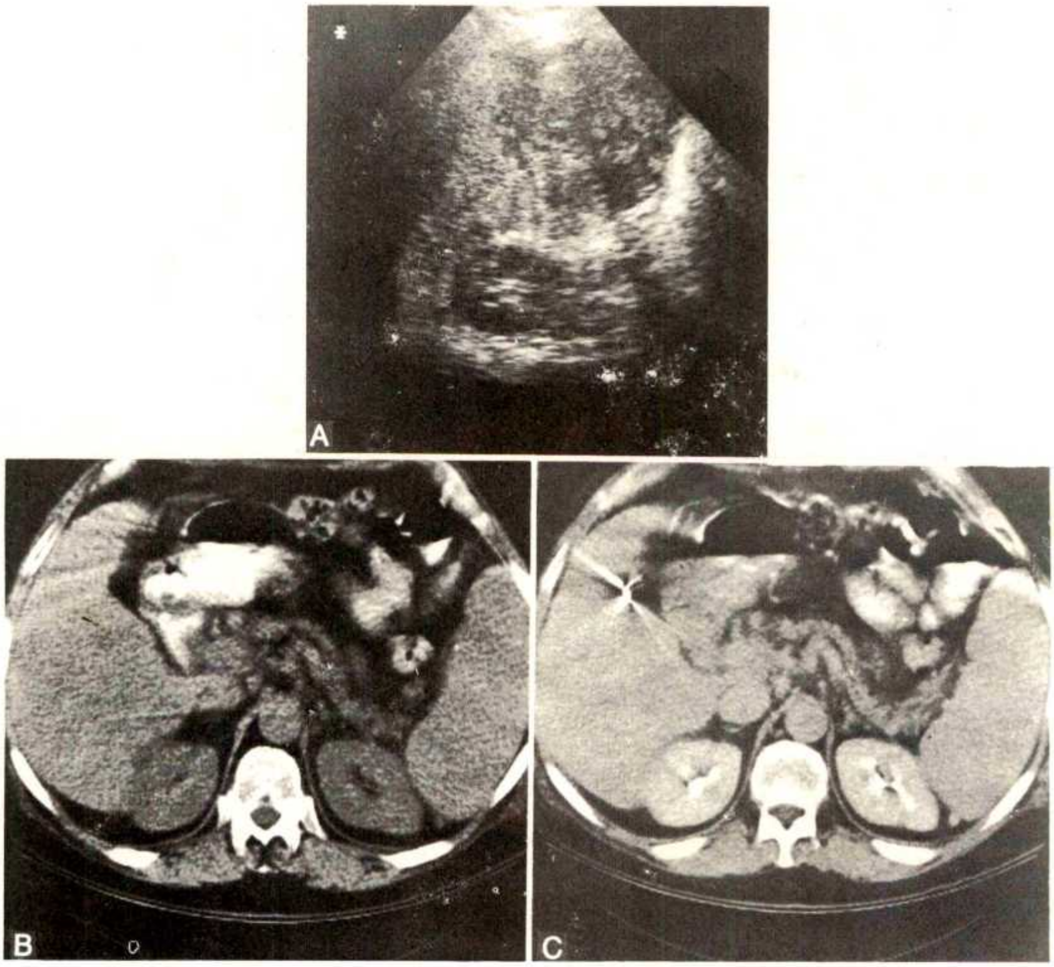

Fig. 4. A, Preoperative US, transverse view, right lobe shows 6 cm hepatocellular carcinoma. Prospectively, mass not visualized on noncontrast and contrast CT scan (**B** and **C**).

may alter the operative plan to extend or limit a resection or may indicate nonresectability.[11, 12, 17] The impact of IOUS was demonstrated in our study in that the operative plan was changed in one third of the patients. IOUS of the liver has been used extensively in the surgical biopsy and resection of hepatocellular carcinomas. It has proved indispensable in the localization and biopsy of small multifocal lesions, particularly in a cirrhotic liver. In one third of cases, these lesions were neither visible nor palpable at surgical exploration.[12] This was confirmed by our study in which 40% of lesions were neither visible nor palpable at surgery. In cirrhotic livers, IOUS can guide subsegmental resection of such lesions in order to preserve as much hepatic parenchyma as possible.

Several conclusions have been drawn from our comparison of preoperative imaging modalities. Although angiography is efficacious in showing hypervascular hepatic masses, there is a decreasing role for angiography in the diagnosis of hypovascular colonic metastases. It should be performed when the surgeon requires a vascular road map or when placement of a hepatic arterial catheter for chemotherapy infusion is planned. The additive effect of preoperative evaluation with CT and US resulted in a lesion-detection rate of 80.8% in the right lobe and 76.3% in the left lobe. Because of this, we recommend that preoperative assessment of liver tumors include both CT and US. With evolving technologic advances in imaging—including CT angiography and newer-generation US and CT scanners, with improved resolution and scanning time—the preoperative accuracy can only increase. Although our current series does not include magnetic resonance imaging, future study will be directed to comparison of MRI to preoperative and intraoperative US.

Forty percent of lesions detected by means of IOUS in our study were not visible or palpable at exploration. Because of this finding and the impact of alteration of the surgical plan in one third of the patients, we recommend that IOUS be performed in patients undergoing surgical treatment of hepatic neoplasm.

Surgical Research Society Abstracts

The 70th Meeting of the Surgical Research Society, organized by the London Hospital Medical College was held at the University of Newcastle on the 6th and 7th July 1989.

Immunomodulation of lymphocytes following circulation through colorectal carcinomas

K.M. Rigg, B. K. Shenton, R.M.R. Taylor and T.W.J. Lennard, *University Department of Surgery, The Medical School, Newcastle upon Tyne, UK*

Malignancy is associated with depression of the host immune response. To determine if passage of lymphocytes through a carcinoma affected their number and function, 26 patients undergoing surgery for colorectal cancer were studied. Blood was sampled from the artery supplying and the vein draining the tumour. Separated lymphocytes were stained with a panel of monoclonal antibodies for T and natural killer (NK) cell subpopulations, along with basal and stimulated interleukin 2 receptor (IL-2R) expression. Lymphocyte transformation (LT) to the T cell mitogen phytohaemagglutinin was assessed by measuring uptake of tritiated thymidine. NK cell activity (percentage killing) was determined using a 4-h ^{51}chromium release cytotoxicity assay with K562 cells as the target.

	NK (%)	Percentage killing	Basal IL-2R	Stimulated IL-2R	LT c.p.m $\times 10^3$
Arterial	27(11–60)	19(3–57)	6(1–30)	76(35–91)	30(4–81)
Venous	35(12–60)*	23(8–42)	6(2–22)	70(31–88)	12(2–72)†

Results expressed as median (range). Significance *versus* arterial *$P<0\cdot002$, †$P<0\cdot02$ (Wilcoxon paired ranks sum test)

The percentage of NK cells was significantly increased in the venous blood draining the tumour compared with the arterial inflow, but overall NK cell activity was unchanged. There were no differences in the T cell subpopulations. Lymphocyte transformation was decreased in the tumour draining blood compared with arterial blood, but IL-2R expression was unaltered. These data suggest that local effects of colorectal cancer may include the ability to down-regulate T cell function, but increase NK cell number. Means of enhancing this antitumour activity therapeutically, possibly by infusion of immunomodulating agents into the portal vein intraoperatively, need to be considered.

Why do women develop breast cysts?

N.J. Bundred, R.R. West, P. Harvey and R.E. Mansel, *Departments of Surgery and Epidemiology, University of Wales College of Medicine, Heath Park, Cardiff, UK*

No risk factors for the development of breast cysts have been described[1]. Follow-up of a group of 639 women with benign nodularity has shown an excess risk of breast cancer among cyst formers alone[2] This study examined whether the risk factors for breast cysts and breast cancer are the same. We have determined prospectively the risk factors for clinically palpable cysts in women seen between 1976 and 1982 in the breast clinic. In all, 352 women developed cysts and 287 had benign nodularity. Univariate analysis showed that age ($\chi^2=140$, $P<0\cdot001$), age at first live birth ($\chi^2=17\cdot54$, $P=0\cdot00015$), older age at menarche ($\chi^2=14\cdot9$, $P=0\cdot0049$), (bra size ($\chi^2=17\cdot68$, $p=0\cdot007$) and shorter duration of contraceptive pill use ($\chi^2=46\cdot56$, $P<0\cdot001$) were all significantly associated with cyst formation whereas smoking, breast feeding and parity were not. Cyst formers were less likely to be current users ($P<0\cdot0001$) or 'ever' users of the pill ($P<0\cdot0001$). Multiple regression analysis revealed three independent factors in predicting cyst formation age ($P<0\cdot0001$), duration of pill use ($P=0\cdot0009$) and bra size ($P<0\cdot002$). The oral contraceptive protects women from development of breast cysts Late age at first live birth is the only recognized risk factor that cyst formers share with breast cancer patients. We conclude that breast cyst formation has a different mechanism from breast cancer development.

Prospective trial of University of Wisconsin solution compared with Marshall's solution for human hepatic allograft preservation

I. Badger, I. Michell, L. Buist, D. Sherlock, A. Awad, J. Buckels and P. McMaster, *The Liver Unit, Queen Elizabeth Hospital, Birmingham, UK*

A new liver allograft perfusion fluid (University of Wisconsin solution, UW) is reported to allow longer preservation than other solutions in animals[1] and humans[2], with good graft function; results of comparative studies are awaited. We report the first, single centre, controlled trial comparing UW to Marshall's solution in hepatic allograft preservation.

Donors were randomized prospectively to receive Marshall's or UW solution. Liver function was assessed by the peak serum aspartate transaminase (AST) and peak prothrombin time (PT) in the first 3 days and on day 7 (AST 7, PT 7) and by biochemical liver function tests at 1 and 3 months. The donor groups were similar for age, cause of brain death, and duration of ventilation. The recipients' ages, genders and diagnoses were comparable.

	UW solution ($n=37$)	Marshall's solution ($n=32$)
Ischaemic time (min)	705 (253–1107)*	346·5 (195–687)
Peak AST (units/l)	748 (135–7000)	771 (210–10 000)
AST 7 (units/l)	47 (13–4011)	65 (18–2829)
Peak PT (s)	31·5 (19–142).16	32 (20–148):16
PT 7 (s)	20 (13–106):16	18 (14–48) 16

Results expressed as median (range) *$P<0\cdot001$ Wilcoxon's two-sample test

Differences in mortality and irreversible graft damage rates were not significant. No side-effects due to UW solution occurred. At 3 months the serum bilirubin in the UW group was 27 *versus* 17, $P<0\cdot05$. This research continues but results suggest that UW solution is at least as effective for hepatic allograft preservation as Marshall's solution despite significantly longer preservation periods.

Does iloprost benefit the patient with claudication? Results of a double-blind placebo-controlled trial

D. Wilkinson, A. Parkin and R.C. Kester, *St. James's University Hospital, Leeds, UK*

Iloprost, a stable prostacyclin analogue, has been evaluated in a double-blind placebo-controlled cross-over trial. Thirty-eight patients with stable claudication (33 male, five female; mean age 63 years, range 41–79) were given iloprost or placebo and then crossed over after 3 months. Daily 7·5-h intravenous infusions were given for 3 days on each occasion at a maximum dose of $2\,\mathrm{ng\,kg^{-1}\,min^{-1}}$. Subjective response, claudication distance (CD), maximum walking distance (MWD), systolic pressure ratios and maximum hyperaemic limb blood flow (LBF) measured with an isotope[1] were recorded before each treatment and then regularly for 3 months.

0007-1323/89/121330-23$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Twenty patients (53 per cent) found iloprost more effective than placebo and two (5 per cent) found placebo more effective than iloprost. Sixteen patients (42 per cent) had no benefit from either treatment. Below are percentage changes from baseline values, showing significant differences between the iloprost and placebo groups (Mann–Whitney *U* test, $^*P<0·05$, $^†P<0·001$).

	CD*	MWD*	LBF (1 day)*	LBF (3 months)†
Iloprost (%)	+74	+80	−7·9	−5·8
Placebo (%)	+35	+44	−5·2	+12·9

The subjective and objective improvements in performance are associated with a fall in hyperaemic blood flow that persists for 3 months after iloprost but recovers after placebo. Iloprost may induce a metabolic adaptation to arterial occlusion which warrants further investigation

Mucosal blood flow following restorative proctocolectomy: pouchitis is associated with mucosal ischaemia

M. Sakaguchi, K. Hosie, R. Tudor, W. Kmiot and M.R.B. Keighley, *Department of Surgery, Queen Elizabeth Hospital, Birmingham, UK*

Restorative proctocolectomy and pouch anal anastomosis provides a means of eradicating disease in ulcerative colitis whilst preserving normal anal function. However, 5–30 per cent of patients develop 'pouchitis', an inflammatory condition associated with diarrhoea, contact bleeding and ulceration on sigmoidoscopy with histological appearance of neutrophil infiltration. As there are occasional difficulties in delivery of the pouch to the pelvis due to inadequate mesenteric length, we have investigated the possibility that pouchitis might be due to pouch ischaemia.

Using the Pf2® (Perimed, Sweden) laser Doppler probe passed via the biopsy channel of a flexible sigmoidoscope, we compared mucosal blood flow in patients following restorative proctocolectomy ($n=14$) and controls with an ileostomy ($n=12$). Multiple flux readings were obtained from the four quadrants of the pouch, the distal ileum above the pouch and from ileostomies. Flux in the pouch (mean 0·88 v, range 0·25–1·8 v) was significantly lower than in healthy ileostomies (1·9 v (0·6–2·7)) ($P<0·01$, Mann–Whitney *U* test). In patients with pouchitis ($n=6$) the flux reading (0·45 v (0·25–0·5)) was significantly lower than in patients with macroscopically normal mucosa ($n=8$) (1·0 v (0·6–1·8)) ($P<0·05$, Mann–Whitney *U* test). There was no significant difference in the flux of J pouches compared with W pouches.

These results suggest that ischaemia may be an aetiological factor in the pathogenesis of pouchitis.

Effect of photodynamic therapy on swine ureters and colonic anastomoses

J.T. Allardice, M.F. Grahn, L. Ilincic, C. Stevens*, J. Van der Walt† and N.S. Williams, *The Surgical Unit, *Bone and Joint Research Unit, and †Department of Morbid Anatomy, The London Hospital, London, UK*

Photodynamic therapy (PDT) is a technique in which a photosensitizing drug (haematoporphyrin derivative (HpD) can be activated by laser light to kill tumour cells selectively. One exciting application would be the intraoperative adjunctive treatment of residual tumour after excision. Before it could be used in humans, however, the effect on normal tissues needs to be determined. We have investigated intraoperative PDT effects on ureters and colonic anastomoses, structures which would be irradiated after rectal cancer resection. Twenty-four miniature piglets (weight 16–51 kg) were given HpD 5 mg/kg 48 h before laparotomy. Eight piglets each received two colonic transections and anastomoses, one receiving ambient light only and the other 40 J/cm² 460–580 nm light delivered from a 600 W tungsten halogen light source passing through a water bath and waveband filter. Nine piglets had a 3-cm ureter illumination with the same light dose. Anastomoses were assessed at 8 days and ureters at 6 weeks by Whitaker's test and measurement of cross-sectional areas (CSA) of biopsies by a computer-based image analysis system with customized software.

	Control*	PDT*
Colon ($n=8,8$)		
Bursting tension (N/cm)	70·2 (60·6–82·5)	76·0 (52·8–85·2)
Hydroxyproline (μg/mg)	14·8 (12·8–17·3)	15·3 (13·8–17·2)
Water content (%)	81·0 (80·1–82·8)	82·7 (80·9–84·7)
Ureter ($n=17,10$)		
Whitaker (cmH_2O)	12·3 (9·0–15·6)	11·6 (7·0–12·5)
Ureter diameter (mm)	2·41 (2·2–2·7)	2·56 (2·4–2·7)
CSA lumen ($\times 10^3$ μm²)	42·6 (21·0–70·0)	32·6 (21·3–70·4)

Values are median (interquartile range) *No significant differences (Mann–Whitney *U* test, $P>0·05$)

All anastomoses were macroscopically perfectly healed. Intraoperative adjunctive PDT can safely irradiate normal ureters and colonic anastomoses and this paves the way for its use in humans.

Prognostic significance of marrow micrometastases in women with early breast cancer

S.J. Kirk, G.G. Cooper, M. Hoper and G.W. Odling-Smee, *Department of Surgery, Queen's University of Belfast and Institute of Clinical Science, Belfast, UK*

Twenty-five patients with early breast cancer (stages I and II) have been studied prospectively to determine the relationship between marrow micrometastases, disease-free interval and survival. Marrow specimens were aspirated from three sites immediately before breast surgery. An immunocytochemical technique using monoclonal antibody LICR.LON M8.4 was employed to detect micrometastases. The minimum follow-up was 38 months.

Twelve of the 25 patients (48 per cent) had micrometastatic lesions in their marrow at presentation. Four of these patients developed distal recurrence during follow-up, causing death in two of them. Five of the 13 patients with no evidence of micrometastases developed distant recurrence and four of them have died.

There was no correlation between the state of the marrow and the development of metastatic disease, although both axillary lymph node status and tumour volume correlated significantly with outcome (both $P<0·025$).

Micrometastatic lesions appear to be common in the marrow of patients with early breast cancer. We have been unable to demonstrate that they have prognostic significance.

Effect of blood in the field of pulsed laser ablation of atherosclerotic tissue

D.C. Mitchell, A. Murray and R.F.M. Wood, *Professorial Surgical Unit, St. Bartholomew's Hospital, London, UK*

Selective ablation of atheroma can be achieved using a 1 μs pulsed dye laser at short wavelengths[1]. During *in vivo* lasing, blood is present in varying quantities between the optical fibre delivery device and the arterial wall. This work explores the effect of the presence of blood on wall penetration and perforation times. Six samples from each of eight normal and eight atheromatous cadaver femoral arteries were subjected to laser energy via a 600-μm diameter quartz fibre held perpendicularly to the wall with a 50 g loading. Laser energy was applied under heparinized saline, whole blood and blood in 1:2 and 1:4 dilutions. The end-point of the experiment was taken as the time to wall perforation. The mean (s.d.) perforation times in s for normal and atheromatous wall at 100 mJ are shown in the *Table*

Tissue	Saline	1:4 dilution	1:2 dilution	Whole blood
Normal wall	9·8 (1·6)	4·3 (0·9)	3·0 (0·5)	1·9 (0·3)
Atheroma	4·2 (0·9)	2·0 (0·7)	1·3 (0·3)	1·0 (0·2)

Blood between the fibre-tip and the arterial wall significantly increases the rate of penetration through both normal artery and atheromatous wall ($P<0·002$, Student's *t* test). The preferential absorption by atheroma compared to normal wall is maintained

($P<0.01$). Haemoglobin strongly absorbs blue-green light and may lower the threshold for the production of the plasma produced by short-pulsed lasers Given careful monitoring of the position of the fibre-tip, the presence of blood, even when diluted by heparinized saline, will therefore improve the efficiency of laser recanalization of a blocked vessel.

A controlled clinical trial comparing low dose heparin with low molecular weight heparin in the prevention of deep venous thrombosis

J.G. Geraghty, G.A. Fielding and D.C. Carter, *Department of Surgery, Royal Infirmary, Glasgow, UK*

Low dose heparin is the standard treatment for the prevention of postoperative deep venous thrombosis but there is now increasing evidence that low molecular weight heparins are an effective and safe alternative to low dose heparins. The aim of this study is to investigate the use of a new low molecular weight heparin (Logiparin) in the prevention of postoperative deep venous thrombosis in a multicentre controlled study

General surgical patients were randomized into three groups. (a) standard heparin (5000 units twice daily); (b) Logiparin (2500 units daily), and (c) Logiparin (3500 units daily) Daily ^{125}I-labelled fibrinogen uptake tests were performed from day 2 to day 7 to detect deep venous thrombosis.

A total of 1290 patients were entered into the study. There was no significant difference in the incidence of positive leg scans in the standard heparin (4·2 per cent, $n=429$) compared with the 3500 units Logiparin group (3 7 per cent, $n=430$), but the incidence of deep venous thrombosis was significantly higher in the 2500 units Logiparin group (7 9 per cent, $n=431$). There was no significant difference in the incidence of severe haemorrhages or the rates of major complications (death, pulmonary embolism, reintervention) in the three groups This study shows that Logiparin, at a dose of 3500 units daily, is a safe and effective means of preventing postoperative deep venous thrombosis in general surgical patients

Timing of antibiotic administration in limb surgery under tourniquet

J.F.R. Robertson, J.B Richardson*, A Roberts†, G. Sweeney† and R. Lindsey†, *City Hospital, Nottingham and *Western Infirmary and †Southern General Hospital, Glasgow, UK*

In limb surgery isolation of the operative site by tourniquet deprives the distal tissues of oxygenated blood and systemic antibiotic. In addition sequestered haematoma following tourniquet release is an ideal site for infection if systemic antibiotic concentration is too low Infection of implanted material is a major complication of limb surgery which may eventually lead to amputation. We have investigated the timing of antibiotic administration in 29 patients undergoing 32 total knee replacements under tourniquet. Patients were randomized to one of three prophylactic systemic antibiotic regimens group 1, 1 g cefamandole 5 min before tourniquet application; group 2, 2 g cefamandole 5 min before tourniquet application, and group 3, 1 g cefamandole 5 min before tourniquet application + 1 g cefamandole 2 min before tourniquet release

Antibiotic concentrations were measured in the serum and in the drain fluid from the wound.

	Group 1 ($n=8$)	Group 2 ($n=8$)	Group 3 ($n=16$)
Serum			
Mean peak concentration (μg/ml)	110	249	130
Mean tourniquet release concentration (μg/ml)	42	45	150
Drain fluid			
Mean tourniquet release concentration (μg/ml)	15	23	44

The drain fluid concentration in group 3 was significantly higher than in the control groups 1 and 2 ($P=0.007$ and $P=0.008$ respectively); there was no significant difference between the two control groups. Drain fluid concentration correlated significantly with the serum concentration at the time of tourniquet release ($r^2=0.554$, $P<0.001$)

Systemic antibiotic therapy for patients having limb surgery under tourniquet should include a tourniquet release dose.

Effect of fibrinolytic enhancement on venous ulcer healing

A.D.R. Northeast, G.T. Layer, M. Stacey, N.M. Wilson, N.L. Browse and K.G. Burnand, *Surgical Unit, St. Thomas' Hospital, London, UK*

Lipodermatosclerosis, which is known to precede venous ulceration, improves when treated with elastic stockings and fibrinolytic enhancement[1] Our aim was to discover if fibrinolytic enhancement would promote ulcer healing when combined with weekly compression dressings consisting of Calaband® (Seton Healthcare Group, Oldham, UK), Elastocrepe® (Smith & Nephew Ltd., Hull, UK) and Tubigrip ® (Seton Healthcare Group) bandages. Arterial Dopplers and rheumatoid serology were performed on entry, and foot volumetry after healing. In all, 126 patients with proven venous ulcers were prospectively randomized to receive either 5 mg stanozolol twice daily or placebo, until healed. Randomization was stratified into three groups based on initial ulcer size.

The treatment group consisted of 62 patients of whom 44 healed, seven remained unhealed at 1 year, and 11 were withdrawn for deterioration, non-compliance, or side-effects. Of the 64 taking placebo, 44 healed, 11 remained unhealed at 1 year, and nine were withdrawn. Kaplan–Meier survival curves showed no significant difference between the groups in the time taken to achieve healing. Our compression regimen healed 83 per cent of those patients who complied with treatment, 53 per cent, within 3 months. This provides baseline data against which new dressing regimens can be tested There is no evidence that fibrinolytic enhancement expedites ulcer healing, or significantly increases the percentage that heal.

1. Burnand KG, Clemenson G, Morland M, Jarrett PM, Browse NL Venous lipodermatosclerosis. treatment by fibrinolytic enhancement and elastic compression. *Br Med J* 1980, **280**: 7–11.

Venous ulceration and the microcirculation of the skin in the calf

H J. Scott, G.M. McMullin, P.D. Coleridge-Smith and J.H. Scurr, *Department of Surgery, UCMSM, The Middlesex Hospital, London, UK*

The microvascular abnormalities in venous ulceration include a pericapillary fibrin cuff, white cell 'trapping' in the lower limb and possible abolition of microcirculatory reflexes

The aim of this study was to determine whether posture affects the microvascular function in the ankle skin of patients with deep venous insufficiency (DVI), and to assess the postural vasoconstriction reflex in these patients.

Duplex ultrasound assigned 50 subjects to normal (N), superficial venous insufficiency (SVI) and DVI categories. Video capillary microscopy, laser Doppler flowmetry (LDF) and transcutaneous oxygen monitoring (P_{tc,O_2}) were used to assess the microcirculation while subjects lay supine for 30 min and then sat with legs dependent for 30 min Indirect body heating (IBH), releasing sympathetic tone, was instituted for 60 min, and the protocol was then repeated. Statistical analysis was by Student's *t* test

All groups showed a rise in the number of visible capillary loops per unit area on dependency (N, SVI, DVI, $P<0.0001$). The P_{tc,O_2} was lower in the DVI group than the other groups ($P<0.001$), the SVI and N groups showed a rise on dependency (N, $P<0.004$, SVI, $P<0.009$). LDF showed decreased blood flow on dependency in all groups (N, SVI, DVI, $P<0.0001$). IBH did not impair this reflex. None of the measured parameters deteriorated during the dependent period.

The postural vasoconstriction reflex remains intact in the DVI group No evidence of a progressive microvascular deficit due to white cell trapping was observed during the course of this study. IBH shows that arteriovenous shunting has no effect on any of the parameters measured

Double-blind placebo-controlled study of indobufen in intermittent claudication

K.T Galvin, K.L. Gorst, J.N. Primrose, P. Kent and R.C. Kester, *Department of Surgery, St. James's University Hospital, Leeds, UK*

Indobufen is a potent oral antiplatelet agent which acts by blocking cyclo-oxygenase. The aim of this study was to assess the value of indobufen in patients with intermittent claudication.

Thirty-three consecutive patients (25 male, eight female, mean age 58 (range 35–72) years), whose intermittent claudication did not improve after 1 month of treatment with placebo were recruited to a double-blind placebo-controlled study of indobufen

Assessment was made using a treadmill test (3·2 km/h 8° slope) assessing initial and maximum claudication distances, pre- and postexercise ankle Doppler studies and radioisotope limb blood flow.

The mean (s.d.) initial claudication distance improved significantly from 90(40)m to 155(132)m on indobufen ($P<0\cdot05$) but not on placebo (82(28)m cf 95(52)m) The maximum claudication distance improved from 168(113)m to 263(188)m ($P<0\cdot05$) on indobufen but not on placebo (122(39)m cf 201(147)m). The improvement in initial (but not maximal) claudication distance was significantly greater with indobufen compared with placebo ($P=0\cdot05$) but Doppler studies and limb blood flows remained unchanged

Indobufen is an effective medical treatment for intermittent claudication

Detection and characterization of arterial thromboses using a platelet specific monoclonal antibody (P256 Fab′)

D.C. Berridge, K.C. Ballantyne, A.C. Perkins*, M. Frier*, M.L. Wastie*, G.S. Makin and B.R. Hopkinson, *Departments of Vascular Surgery and *Medical Physics, University Hospital, Queen's Medical Centre, Nottingham, UK*

Arteriography does not reliably distinguish between acute and chronic arterial occlusions, and does not select those patients likely to benefit from thrombolysis We have investigated ten patients with acute lower limb ischaemia by arteriography and ^{111}In-labelled P256 Fab′ platelet specific monoclonal antibody imaging; 20 MBq ^{111}In-P256 was administered intravenously and patients were imaged after 5 h.

Six patients were treated with intra-arterial thrombolysis Three of these patients had highly positive ^{111}In-P256 uptake, thrombolysis was successful and the vessel remained patent. However, in the three patients with negative images, despite initially successful thrombolysis, immediate rethrombosis occurred in two, only one remaining patent

The remaining four patients were not treated with thrombolysis. Two had positive ^{111}In-P256 images, demonstrating clinically occult bilateral iliac aneurysms with distal embolization in one, and two separate sites of critical stenoses (90 per cent) in the other. In the two patients with negative images, thrombolysis was contraindicated due to the presence of a Dacron® (Du Pont) graft (one) or deteriorating renal function (one) In both these patients the duration of history was >4 weeks.

This pilot study has demonstrated that ^{111}In-P256 imaging can identify sites of acute arterial thrombosis and provide additional information to arteriography, and may identify those patients most likely to benefit from thrombolysis

Epidemal growth factor receptor (EGFR) status: a clinically useful prognostic indicator in axillary node negative breast cancer

S. Nicholson, J.R.C. Sainsbury, A.L. Harris* and J.R. Farndon, *Departments of Surgery and *Medical Oncology, University of Newcastle upon Tyne, UK*

The presence of axillary lymph node metastases is the most powerful prognostic indicator in breast cancer Not all surgeons, however, routinely sample the axillary lymph nodes and these data do not predict the likelihood of response to either systemic adjuvant therapy or to systemic therapy at relapse.

In a series of 221 patients with operable breast cancer, followed for up to 5 years after surgery, EGFR expression was associated with poor prognosis ($P<0\cdot001$, log rank) and was inversely related to oestrogen receptor (ER) status ($P<0\cdot0001$) In a multivariate analysis of survival data, EGFR status was the only significant prognostic variable in patients with negative and unsampled (clinically negative) axillary lymph nodes

Of 99 out of 221 patients with a documented recurrence, 72 had assessable responses to systemic endocrine therapy. EGFR expression was significantly associated with a lack of response ($P<0\cdot01$) and rapid disease progression ($P<0\cdot005$, log rank), and appeared to be more useful than ER status in predicting response to endocrine therapy.

In conclusion, EGFR status was a significant prognostic indicator in patients with clinically or histologically negative axillary lymph nodes, and predicted response to systemic endocrine therapy in patients with recurrent breast cancer with greater utility than ER status EGFR status may prove to be valuable in selecting node negative patients and those whose nodes have not been sampled for adjuvant systemic endocrine therapy.

Epidermal growth factor receptor (EGFR) in primary breast cancer

A. Locker, S.J. Lewis, I.O. Ellis, C.W. Elston and R.W. Blamey, *City Hospital, Nottingham, UK*

EGFR measured by binding assay and immunohistochemistry has been claimed to be a powerful prognostic factor in breast cancer[1].

Ninety invasive breast cancers held in freeze-dried storage were stained by an indirect peroxidase method with a monoclonal antibody to EGFR The staining was graded by two observers and the results were correlated with a number of established tumour prognostic variables, together with disease-free interval (DFI) Actuarial methods were used in the determination of DFI The maximum follow-up was 36 months

Seventy-five tumours were EGFR negative and 13 were EGFR positive. Results showed that (a) there was a significant inverse correlation between EGFR staining and oestrogen receptor (ER) measured by the dextran-coated charcoal method, (b) there was no relationship of EGFR to histological grade; and (c) the combination of EGFR positivity and ER negativity predicts early recurrence

EGFR measured by immunocytochemistry in primary breast cancer is confirmed as a prognostic factor in the prediction of early recurrence. However, even in combination with ER, prediction is not as powerful as that attained by histological grade.

1. Sainsbury JRC, Farndon JR, Needham GK, Malcolm AJ, Harris AL. Epidermal growth factor receptor status as predictor of early recurrence and of death from breast cancer *Lancet* 1987, **i**. 1398–402

Prognostic value of immunoperoxidase staining with monoclonal antibodies NCRC-11 and 3E1.2 in breast cancer

I.M. Muir, S.A. Stocker*, R.C. Bennett and I.F.C. McKenzie* (introduced by R.W. Blamey), *Departments of Surgery and *Pathology, University of Melbourne, Australia*

Monoclonal antibody (MoAb) NCRC-11 has been shown to identify an antigen which has prognostic significance in patients with breast cancer[1] However, other studies with this and other MoAbs have failed to show prognostic value.

The present study comprised 483 patients in a second centre with a minimum follow-up of 5 years. Paraffin blocks of primary tumour were stained with NCRC-11 and with a second MoAb, 3E1 2. Sections were examined by light microscopy and given a score on the scale 1–4

For any tumour the staining scores with both antibodies were similar, $r=0\cdot70$, $P<0\cdot001$.

Life-table analysis showed that both MoAbs related to survival NCRC-11, together with lymph node positivity, progesterone receptor status, size and age, was sustained as an independent variable in a Cox multivariate analysis ($\chi^2=5\cdot9$, $P<0\cdot02$)

3E1 2 related to survival only in lymph node negative patients ($\chi^2=10\cdot7$, $P<0\cdot001$).

NCRC-11 is confirmed in a separate series as a powerful prognostic factor in breast cancer.

1 Ellis IO, Hinton CP, MacNay J *et al* Immunocytochemical staining of breast carcinoma with the monoclonal antibody NCRC-11 a new prognostic indicator *Br Med J* 1985, **290**. 881–3

Tumour bed biopsy: a new prognostic indicator following conservative management of early breast cancer

R. Carpenter, M. Cross, A. Herbert, G. Royle and I. Taylor, *Royal South Hampshire Hospital, Southampton, UK*

Breast cancer recurrence following lumpectomy and radiotherapy cannot be predicted in individual women. We have investigated the significance of tumour foci in bed biopsies taken at the time of lumpectomy in a consecutive series of 117 women with early breast cancer treated at one unit since 1986.

Following lumpectomy, residual tumour was found in 32 (27·4 per cent) of cases, in 17 as invasive and in 15 as *in situ* cancer. Management by breast irradiation was changed as a reult of bed biopsy findings in nine women who underwent mastectomy.

After 3·5 years 84·6 per cent of women with negative biopsies were alive without disease compared with 62·3 per cent with positive biopsies (life-table analysis). When other prognostic factors were considered, 56·3 per cent with nodel metastases were alive and disease-free compared with 94·4 per cent of node negative cases (χ^2 test, $P<0\cdot05$). When both node and bed biopsy positivity were considered, a group ($n=10$) was identified which fared particularly badly, only 35·5 per cent surviving disease-free compared with 95·7 per cent in the group ($n=62$) with neither risk factor (χ^2 test, $P<0\cdot01$). All groups were equivalent for age and oestrogen receptor status.

Bed biopsy status is an important risk factor in the assessment of the suitability of women for conservative management of early breast cancer.

Natural history and origin of the populations of breast cysts

J.M. Dixon, W.N. Scott and W.R. Miller, *Breast Unit, University Department of Surgery, Royal Infirmary, Edinburgh, UK*

Two populations of breast cysts can be defined on the basis of electrolyte composition of cyst fluid (apocrine cysts, $Na^+:K^+<3$; flattened cysts, $Na^+.K^+\geqslant 3$) It has been reported that cyst type tends to remain constant in individual patients and that multiple cysts are more likely to be of apocrine type[1]. Recently these findings have been challenged and the view expressed that flattened cysts arise from apocrine cysts by increase in size or ageing[2].

In the present study we have analysed 1059 cysts aspirated from 420 patients over an 8-year period. Cyst type remained constant in 62 per cent of 237 patients with multiple cysts. The ratio of apocrine:flattened cysts (A:F) increased as the total number of cysts aspirated increased.

	No of cysts aspirated				
	1	2, 3	4, 5	6–10	7–10
Ratio A:F	1·18	2·30	3·15	4·03	12·40

Neither volume (studied in 100 patients) nor length of history (studied in 75 patients) correlated with composition.

In conclusion, cyst type remained constant in 62 per cent of patients and multiple cystic disease is usually apocrine cystic disease. Flattened macrocysts do not arise from apocrine macrocysts by expansion or ageing.

Importance of routine mammography in the management of patients with small breast cancers

J.M. Dixon and U. Chetty, *Breast Unit, Department of Surgery, Royal Infirmary, Edinburgh, UK*

It is not universal practice to perform mammography in all patients undergoing conservation therapy for breast cancer This study assesses whether routine mammography provides valuable information in the assessment of which small breast cancers are suitable for breast conservation.

Two hundred patients aged 70 years or less with a single palpable breast cancer measuring less than 4 cm staged T1 or T2, N0 or N1 and M0 were studied.

In 149 (74·5 per cent) mammography confirmed a localized malignant lesion, while in 32 (16·0 per cent) no suspicious lesion was identified. The remaining 19 patients had mammographic abnormalities not evident on clinical examination. Six had extensive areas of suspicious microcalcification associated with the carcinoma; six patients were considered mammographically to have more than a single focus of carcinoma; and seven patients had contralateral suspicious lesions. Subsequent histology showed all six areas of microcalcification to be associated with *in situ* malignancy and all six patients with more than a single mammograpic lesion were confirmed to have multifocal disease Five of the seven contralateral lesions were shown to be malignant.

In this study mammography indicated that 6·0 per cent of patients (those with microcalcification or multifocal disease) were unsuitable for breast conservation. A further 2·5 per cent of patients were found to have contralateral carcinomas. Routine mammography is essential in the management of patients with small breast cancers.

Peritoneal cytology for 'query appendicitis'

M.N. Vipond, S. Paterson-Brown, M.R. Tyrrell, J.N. Thompson, D. Coleman* and H A.F. Dudley, *Academic Surgical Unit and *Department of Cytology, St. Mary's Hospital, London, UK*

Overall rates of diagnostic error for appendicectomy have been reported as 25 per cent and this figure can rise to 40 per cent in women of child-bearing age. We have evaluated the role of peritoneal cytology (PC) in discriminating which patients with right iliac fossa pain should undergo operation[1].

Fifty-one patients with acute right iliac fossa pain were classified into two groups according to a prior clinical decision· (I) definitely appendicitis and (II) 'query appendicitis' (including all women). Peritoneal aspirates, obtained via a fine catheter, were examined microscopically and the peritoneal neutrophil percentage (PNP) was counted. All patients in group I proceeded to appendicectomy and those in group II to laparoscopy, thus giving a final diagnosis in all.

All 16 patients in group I had appendicitis and the PNP was > 50 per cent in all. Of the 35 patients in group II, 18 required operation: PNP was > 50 per cent in 17 with appendicitis and fresh blood was aspirated in one patient with ectopic pregnancy. Seventeen patients in group II did not require operation the PNP was < 10 per cent in 15 and > 50 per cent in two, both patients with acute pelvic inflammatory disease (PID).

In this study PC has a sensitivity of 97 per cent and a specificity of 88 per cent. The benefit of PC is restricted to the 'uncertain group'. We suggest that PC should be applied to this group: if the result is positive then the patient should proceed to laparotomy unless PID is a clinical possibility in which case laparoscopy is required to avoid an unnecessary laparotomy.

1. Stewart RJ, et al Fine-catheter aspiration cytology of peritoneal cavity improves decision-making about difficult cases of acute abdominal pain *Lancet* 1986; **ii** 1414–15.

Strip testing of the peritoneal exudate reliably identifies intraperitoneal inflammation

R.J.L. Williams, J. Lavelle, M.N. Vipond, E.R.T.C. Owen and P.J. Guillou, *Academic Surgical Unit, St. Mary's Hospital, London, UK*

Cytological examination of peritoneal fluid obtained via a fine catheter is a sensitive technique for identifying patients with intraperitoneal inflammation, a preponderance of neutrophils possibly indicating the need for surgical exploration[1]. However, cytology may be time consuming and observer dependent. Chemical strip tests of the type used in routine urine testing detect leucocytes by an esterase reaction and might simplify the examination of peritoneal fluid for neutrophils. We have compared conventional cytology with strip testing of the same peritoneal fluid. Peritoneal aspirates were obtained just before laparotomy in 50 patients who were undergoing either elective abdominal surgery for non-inflammatory conditions or emergency laparotomy for intraperitoneal sepsis. Chemical testing was performed with Nephur-Test + Leuco (NTL, Boehringer Corporation, Lewes, UK) and Cytur-Test (CT) strips, for which positive criteria were > 75 and > 25 leucocytes/μl respectively. Conventional cytology was considered positive if the aspirate contained >50 per cent neutrophils. Results were as follows:

	NTL	CT	Cytology
Emergency surgery group (positive tests/n)	22/23	19/19	14/16
Elective surgery group (positive tests/n)	1/24	0/27	0/24
Sensitivity (%)	96	100	88
Specificity (%)	96	100	100

Strip testing is quicker and simpler method of assessing the peritoneal exudate for the presence of leucocytes and appears to be as specific and sensitive as standard cytological examination.

1. Stewart RJ et al. Fine-catheter aspiration cytology of peritoneal cavity improves decision-making about difficult cases of acute abdominal pain. *Lancet* 1986; **ii**: 1414–5.

Targeting of microdiscs in neutrophils to rabbit appendix abscess

M. Bhamra, S.A. Whawell, J.F. Dye, P.F. Tufton* and H.A.F. Dudley, *Academic Surgical Unit, St. Mary's Hospital, London and *Royal Signals and Radar Establishment, Malvern, UK*

The ability to deliver drugs to a specific focus of infection has been a much sought-after goal. The main obstacle is the reticuloendothelial system (RES) In order to reduce RES uptake we investigated the possibility of 'hiding' microdiscs within neutrophils and delivery to an experimental appendix abscess

The abscess was created in 11 New Zealand white rabbits by luminal obstruction with a balloon catheter. In six animals 2×10^6 white blood cells (WBC) were separated from peripheral blood and incubated with 3 μm ^{76}arsenic-labelled silicon microdiscs. In a further five animals microdiscs were injected without prior incorporation into the white cells The animals were sacrificed 2 h later and radioactivity counts were determined from homogenized tissue of appendix and an equivalent length of normal jejunum

	Microdiscs in WBC ($n=6$)	Microdiscs alone ($n=5$)	P*
Ratio of radioactive counts, appendix:jejunum (c.p.m./g)	2·47	0·96	<0·001

* Mann–Whitney U test

These results demonstrate that intracellular microdiscs can be actively targeted to an area of sepsis, evading the RES, and could contribute to the local management of surgical sepsis.

Peritoneal fibrinolytic activity and adhesions

M N. Vipond, S.A. Whawell, T. Harbourne, J.N. Thompson and H.A.F. Dudley, *Academic Surgical Unit, St. Mary's Hospital, London, UK*

A unifying hypothesis[1] states that peritoneal fibrinolytic activity is reduced in conditions that lead to adhesion formation. We have examined this hypothesis by measuring plasminogen activator activity (PAA), tissue plasminogen activator (t-PA) and plasminogen activator inhibitor (PAI) of human peritoneum.

Peritoneal biopsies were obtained operatively using a 6mm biopsy punch from normal ($n=10$) and inflamed ($n=7$) human peritoneum. The samples were homogenized, and assayed by fibrin plate lysis (functional assay) for PAA and by ELISA for both t-PA and PAI.

	Normal	Inflamed	P*
PAA (units/cm²)	12·0	0·0	0·001
t-PA (ng/ml)	1·03	1·02	n.s.
PAI (ng/ml)	0·0	8·8	0·001

* Mann–Whitney U test

These results demonstrate that functional fibrinolytic activity present in normal peritoneum is abolished in inflammation. The elaboration of PAI appears to be central to this change in functional activity. Modification of this response may ultimately be of benefit in prophylaxis of adhesion formation.

Prospective randomized study of ingrowing toenail management

J.D. Greig, J.H. Anderson, A.J. Ireland and J.R. Anderson (introduced by H.J.G. Burns), *University Department of Surgery, Royal Infirmary, Glasgow, UK*

A prospective, single-blind, randomized, parallel-group study compared total nail avulsion (group I), nail edge excision alone (group II) and nail edge excision with germinal matrix phenolization (group III). One hundred and sixty-three consecutive patients with ingrowing toenails in whom conservative treatment had failed and who had not had previous surgery were recruited. Bacteriological cultures of nail bed discharge were taken pre- and postoperatively Patients were assessed at 2 weeks and 1 year after surgery. Demographic data for the three groups were comparable. Preoperative infection did not predispose to postoperative sepsis. Although most wounds in the phenolized group (III) were moist at 2 weeks, only seven (12 per cent) were infected The incidence of recurrence was 73 per cent (group I), 73 per cent (group II) and 9 per cent (group III), respectively The incidence of recurrence (9 per cent) in the phenolized group (III) was significantly lower ($P<0·001$) than in the other two groups. These results are comparable to other series[1] However, assessment was independent in our study, and follow-up was prolonged. Nail edge excision with phenolization is a logical and effective treatment for ingrowing toenails. Non-ablative procedures should have no place in hospital practice, except where there is an absolute contraindication to the use of phenol.

Modulation of the neutrophil respiratory burst and alveolar capillary permeability in sepsis-induced acute respiratory distress syndrome by the non-steroidal anti-inflammatory drug, ibuprofen

P.D. Carey, K. Byrne, J.K. Jenkins, A.M. Schneider, T.D Sielaff, C.R. Blocher, A.A. Fowler and H.J. Sugerman (introduced by W.A. Tanner), *Departments of Surgery and Medicine, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia, USA*

The effects of ibuprofen, a cyclo-oxygenase inhibitor, on phagocyte respiratory burst and parameters of alveolar capillary membrane permeability were studied in a porcine model of septic acute respiratory distress syndrome. Anaesthetized swine (20–25 kg) were intubated and mechanically ventilated ($FiO_2 = 0·5$). Control animals (C) received a sham infusion of 0·9 per cent NaCl, septic animals (Ps) received a 1 h infusion of live *Pseudomonas aeruginosa* (5×10^8 colony forming units ml^{-1} at 0·3 ml 20 kg^{-1} h^{-1}) and a treated group (I) received Ps plus ibuprofen (12·5 mg kg^{-1} at 0 and 120 min) Peripheral blood neutrophils (PMN) were isolated and bronchoalveolar lavage (BAL) was performed to study BAL protein (BAL-P) and alveolar neutrophil percentage (AN % – percentage total cell harvest) at 0 and 5 h. PMN superoxide ($O_2\cdot$) production was assessed as the maximum initial rate of superoxide dismutase inhibitable cytochrome C reduction (PMA stimulation)

	PMN $O_2\cdot$ (nmol min^{-1})		BAL-P (μg ml^{-1})		AN (%)	
Group	0 h	5 h	0 h	5 h	0 h	5 h
C ($n=6$)	1·05(0·2)	1·23(0·2)	171(17)	145(19)	3(1)	3(2)
Ps ($n=5$)	0·93(0·1)	8·05(0·7)*	170(17)	690(150)*	3(2)	25(8)*
I ($n=5$)	1·07(0·2)	4·13(0·8)	114(19)	143(23)	2(1)	5(1)

Values are mean (s.e.m.) $P<0·01$ Ps *versus* C and I, ANOVA

Ibuprofen attenuated PMN generation of $O_2\cdot$, indicating a down-regulation of oxidant generation, *in vivo*, following sepsis. Ibuprofen also prevented increased airways protein and neutrophil accumulation indicating protection of the alveolar epithelial membrane. This dual effect of ibuprofen may have important implications in the treatment of acute respiratory distress syndrome in forthcoming human trials.

Randomized trial of streptokinase and tissue plasminogen activator in peripheral arterial thrombolysis

D.C. Berridge, R.H.S. Gregson*, G.S. Makin and B.R. Hopkinson, *Departments of Vascular Surgery and *Radiology, University Hospital, Queen's Medical Centre, Nottingham, UK*

Fifty-five patients have been recruited into a randomized parallel-group comparison of three thrombolytic regimens. Eighteen patients received intra-arterial streptokinase (SK), 19 received intra-arterial tissue plasminogen activator (IA t-PA) and 18 patients received intravenous t-PA (IV t-PA). There were no significant differences in age, duration of history, length of occlusion or presence of neurosensory deficit between the groups.

Initially successful lysis was significantly greater with IA t-PA than with either SK ($P<0·04$) or IV t-PA ($P<0·003$). The duration of therapy varied from a median of 30 h with IA t-PA to 40 h with SK (not significant). The mean increase in ankle:brachial index following IA t-PA (0·59 (0·28)) was significantly higher ($P<0·001$) than for either SK (0·31 (0·33)) or IV t-PA (0·25 (0·31)). Limb salvage was achieved in 79 per cent (IA t-PA), 50 per cent (SK) and 44 per cent (IV t-PA).

Haemorrhagic complications occurred in five patients following SK administration (two major, three minor), and in 11 patients following IV t-PA administration (one cerebrovascular accident, three major, four minor). In contrast there were no periods of hypotension, no transfusions were required, and only one minor haemorrhage occurred following IA t-PA ($P<0·05$).

IA t-PA provides a more effective, safer fibrinolytic treatment than conventional therapy with SK. Systemic t-PA administration has not been as successful, with a significantly higher risk of haemorrhagic complications

Restriction fragment length polymorphisms in the region of the oestrogen receptor gene: a new prognostic indicator

M.J. Kerin, R.P. Waldron, J. Neilan*, F.X. Gannon* and H.F. Given, *Departments of Surgery and *Microbiology, University College and University College Hospital, Galway, Ireland*

Oestrogen receptors are important markers of mammary tumour hormonal dependence and prognosis. The oestrogen receptor (ER) gene is a 'candidate gene' for mutation or abnormal transformation which may predispose to neoplasia. Cloning of the ER copy DNA (ERcDNA) has allowed comparison of the ER gene from breast cancer patients with that from normal subjects.

We have studied total genomic DNA prepared from tumour tissue of 81 patients with breast cancer and lymphocytes from 70 normal volunteers. The DNA was digested by seven different restriction endonucleases and restriction fragment length polymorphisms (RFLPs) identified by southern blot analysis using probes pOR_8 and pOR_{21} from the 5′ translated and 3′ untranslated regions of human ERcDNA respectively. Analysis of Msp1, Rsa1, Hae2 and Sau3a digests failed to demonstrate any consistent differences after hybridization and autoradiography. Digestion with $EcoR_1$, Taq_1 and Sac_1 revealed RFLPs specific to tumour patients (*Table 1*).

Table 1 *Summary of tumour-specific polymorphisms*

Restriction enzyme	Probe	Fragment size (kilobases)	Frequency of occurrence	
			Tumour	Control
$EcoR_1$	pOR_{21}	5·0	2/15	0/50
Taq_1	pOR_{21}	2·0	3/45	0/50
Sac_1	pOR_{21}	4·76	19/21	21/21

All seven patients showing these polymorphisms had advanced stage III disease at presentation and four demonstrated disease progression at a mean follow-up of 18 months.

We conclude that ER gene analysis not only provides further insight into the aetiology of breast cancer but may be of considerable prognostic significance.

Antirejection therapy in renal transplantation: OKT3 or methylprednisolone?

M.L. Nicholson, P.M. Williams, P.K. Donnelly, P.S. Veitch and P.R.F. Bell, *Renal Transplant Unit, Leicester General Hospital, UK*

The development of monoclonal antibodies against human lymphocytes has provided a new therapeutic alternative in the treatment of acute rejection.

In this study the success of antirejection therapy was evaluated in 65 cadaveric renal allografts immunosuppressed with cyclosporin. All first rejection episodes were treated with 0·5 g methylprednisolone (MP) given daily for 3 days (group A) Second rejection episodes were treated with either a further 3-day course of MP (group B) or a 10–14-day course of the monoclonal antibody OKT3 (group C)

Group	Rejection reversals*	Grafts surviving*	Peak creatinine† (μmol/l)	Creatinine at 6 months† (μmol/l)
A ($n=41$)	29 (71)	34 (83)	312 (116)	203 (78)
B ($n=14$)	9 (64)	12 (86)	320 (128)	230 (71)
C ($n=10$)	10 (100)	8 (80)	480 (174)	160 (42)
A *versus* B	n.s	n.s	n.s.	n.s.
A *versus* C	n.s	n.s.	$P=0·022$‡	n.s.
B *versus* C	$P=0·047$§	n.s	$P=0·036$‡	$P=0·024$‡

*Number (percentage), † mean (s.d.), n.s., not significant; ‡ Mann–Whitney *U* test; § Fisher's exact test

When treating second rejection episodes, a higher reversal rate was achieved with OKT3 therapy The most severe rejection episodes, as judged by peak creatinine, were found in the OKT3 group Despite this the creatinine at 6 months was lower in the OKT3 group than in either of the MP groups

In conclusion, treatment of second rejection episodes with OKT3 gives improved graft function at 6 months.

Tumour-derived suppressor factor impairs the autocrine function of lymphokine-activated killer cells

S.S. Somers, K. Nye, J.F. Dye and P.J. Guillou, *Academic Surgical Unit, St. Mary's Hospital, London, UK*

Previous work suggests that the immunotherapy of malignant disease, either with recombinant cytokines or adoptive transfer of cytokine-activated lymphocytes, fails because of immunosuppressive factors produced by tumour cells[1] Cytokines normally bind to specific receptors on the lymphocyte surface and cause activation by inducing intracellular second messengers. These can be detected as inositol phosphates (IP) and cyclic AMP (cAMP).

We have measured the production of intracellular IP_2, IP_3 and cAMP in lymphocytes activated by the cytokines interleukin 2 (IL-2), interleukin 4 (IL-2) and prostaglandin I_2 (PGI_2), in the presence and absence of tumour-derived suppressor factor (TDSF).

TDSF did not influence the production of IP_2 or IP_3 signals. The PGI_2 induced cAMP signal was reduced by 90·6 per cent at peak of control response (30 s) and the integrated response was reduced by 65 per cent The AMP signal is implicated in the secretion of interferon γ (IFN-γ), which is vital for activation of lymphocyte cytotoxicity towards tumour cells[2] We measured the production of IFN-γ by activated lymphocytes and found it to be reduced by 70 per cent in the presence of 25 per cent TDSF.

We conclude that TDSF subverts the immune response by inhibiting the autocrine secretion of IFN-γ at the second messenger level. This knowledge may lead to the design of more effective immunotherapeutic protocols

2. Giovarelli M, Santoni A, Jemma C *et al.* Obligatory role of IFN-γ in induction of lymphokine-activated and T-lymphocyte killer activity, but not boosting of natural cytotoxicity. *J Immunol* 1988, **141**: 2831–6.

Reduced tissue fibrinolysis in a model of hind limb venous hypertension

A.D.R. Northeast, H. Gajraj, K.G. Burnand and N.L. Browse, *Surgical Unit, St. Thomas's Hospital, London, UK*

Pericapillary fibrin deposition is found in association with venous ulceration[1]. Interstitial tissue fibrinolysis has been shown to be depressed in the legs of patients with healed venous ulcers or simple varicose veins who had proven venous valvular incompetence[2]. The aim of this study was to discover whether induced venous hypertension caused changes in tissue (skin) fibrinolysis.

Eight canine common femoral side-to-side arteriovenous fistulae were formed. Radiolabelled fibrin clots were produced by subcutaneous injection of ^{125}I-labelled fibrinogen and thrombin 8 weeks after fistula formation. The lysis rate was measured, and a clearance half-life was calculated[2]. Skin was taken from the midpoint of the affected and control hind limbs, snap frozen, homogenized, and assayed for tissue plasminogen activator (t-PA) with a sensitive bioimmunoassay.

	t-PA level (units/g)	Fibrin clearance ($t_{1/2}$)
Hypertensive limbs	594 (482–925)	6 (5–9)
Control limbs	849 (712–2044)	5 (4–6)

Values are median with range in parenthesis

Fibrin clearance was prolonged and the t-PA level was lower in the hypertensive limb in seven out of eight cases ($P<0{\cdot}05$ for both sets of data on the Wilcoxon test).

These results support the concept that venous hypertension causes a diminution in tissue fibrinolysis.

Ranolazine: a new drug with beneficial effects on quality of renal preservation

J.P.A. Lodge, R. Upadhyaya, F.T. Lam and G.R. Giles, *University Department of Surgery, St. James's University Hospital, Leeds, UK*

Ranolazine (Syntex Pharmaceuticals, Maidenhead, UK) is a new drug with a novel mode of action as a metabolic modulator and membrane stabilizer. In this double-blind trial of 30 bilaterally nephrectomized pigs, the left kidney was autotransplanted after preservation for 24 h in phosphate buffered sucrose (PBS140). Ten pigs were randomized to each of three groups: A, placebo; B, intravenous ranolazine before nephrectomy and in PBS140 flush and storage; and C, intravenous ranolazine after transplantation. Renal function was studied by measurement of perioperative blood flow; postoperative urine output; serum and urine urea, creatinine and osmolarity; inulin, PAH and lithium clearances for 14 days. Decoding of the first 25 animals allows us to report the results in the *Table*.

	Group A ($n=9$)	Group B ($n=9$)	Group C ($n=6$)
Death in renal failure	2	1	3
Weight (kg)	31·1 (0·7)	31·9 (1·8)	32·6 (2·2)
Peak serum urea (mmol/l)	43·4 (6·0)	28·5 (3·4)	33·4 (3·8)
Peak serum creatinine (μmol/l)	1063 (140)	754 (93)	840 (62)
Time to creatinine <200 μmol/l (days)	10·2 (4·2)	6·4 (0·9)	8·7 (2·3)
Peak urine flow (ml/h)	226 (23)	215 (28)	208 (123)
GFR at day 7 (ml/min)	16·4 (6·1)	56·6 (17·8)*	11·0 (7·1)
Peak GFR (ml/min)	47·8 (12·2)	104·8 (23·3)†	45·0 (21·7)

Values are mean (s.e.m.), GFR, glomerular filtration rate; * $P<0{\cdot}05$, † $P<0{\cdot}05$ (Student's t test)

This detailed study shows that porcine kidneys preserved in PBS140 containing ranolazine achieved superior renal function within 1 week of transplantation, and this benefit remained significant at 2 weeks

Modulation of colon cancer fatty acids by dietary n-3 lipids results in tumour growth suppression

M. Sakaguchi, S. Rowley, N. Kane, C. Jones, A. Davies, P. Baker, M. Keighley and J.P Neoptolemos, *University Department of Surgery and Dudley Road Hospital, Birmingham, UK*

Colorectal cancer is linked epidemiologically to a high saturated fat diet, perhaps by increasing the availability of arachidonic acid and its metabolites which are tumour promoting Paradoxically this also suggests the possibility of treatment by dietary manipulation In order to investigate this, 1×10^7 colo-320 tumour cells were injected subcutaneously into each of 30 nude mice receiving either a 20 per cent saturated fat diet or 20 per cent n-3 polyunsaturated fat (Maxepa®, Duncan, Flockhart and Company, Greenford, UK) diet over 4 weeks Tumour size was determined by *in vivo* cast modelling (volume) during growth and by weight following excision. Tumour lipids were extracted and analysed by advanced tube capillary gas chromatography (sensitivity in the pmol range).

Tumour growth (mean (s d)) was reduced by the n-3 diet at 3 weeks (0·14 (0·05) *versus* 0·09 (0·04) cm^3, $P<0{\cdot}02$) and 4 weeks (0·61 (0·38) *versus* 0·29 (0·16) cm^3, $P<0{\cdot}02$; 0·60 (0·34) *versus* 0·28 (0·16) g, $P<0{\cdot}02$). There was reduction of tumour arachidonate by the n-3 diet (0·72 (0·18) *versus* 0·44 (0·16) nmol/mg protein, $P<0{\cdot}02$) and enhanced n-3 fatty acids especially eicosapentanoate (trace *versus* 0·82 (0·13), $P<0{\cdot}005$), 22.5 n-3 (0·18 (0·18) *versus* 0·78 (0·24), $P<0{\cdot}005$) and docosahexanoate (0·15 (0·1) *versus* 0·73 (0·34), $P<0{\cdot}005$) The effects were particularly striking in the tumour phospholipid fraction (i.e. the major fraction of arachidonic acid metabolism) (two-tailed Mann–Whitney U test).

These original findings show that dietary n-3 fats not only reduce the arachidonate content of a growing tumour, but greatly enhance the content of docosahexanoate and eicosapentanoate which are potent inhibitors of enzymes producing tumour-promoting arachidonate metabolites. This dual mechanism may explain the striking tumour growth suppression by n-3 fats.

Increased arachidonic acid in experimental colorectal tumours

M.L. Nicholson, J.P. Neoptolemos*, H.A. Clayton, I C. Talbot† and P.R.F. Bell, *Departments of Surgery and †Pathology, Leicester University and *Department of Surgery, Birmingham University, UK*

The relationship between dietary fat and colorectal cancer is not fully understood. This study examines the effect of dietary fat on colonic tumour induction and membrane fatty acid composition in male Wistar rats.

Fifty rats each were fed on either diet A (5 per cent saturated fat) or B (20 per cent saturated fat). Colorectal tumours were induced by intraperitoneal injection of azoxymethane (AOM) ($n=40$) and control animals received saline ($n=10$). Between 6 and 26 weeks animals were killed at intervals for histology and lipid analysis. Membrane fatty acids in erythrocytes, adipose tissue, colonic mucosa and colorectal tumours were determined by gas liquid chromatography.

Animals fed on diet B developed more tumours (1·86 (0·43) per rat) than those fed on diet A (0·8 (0·28) per rat) (mean (s e m.), $P=0{\cdot}03$, Mann–Whitney U test). Lipid analysis demonstrated a markedly increased content of arachidonic acid in tumours compared with colonic mucosa (*Table*) Furthermore, dietary fatty acid composition was found to influence the profile of membrane fatty acids in colonic mucosa

	Palmitic acid	Stearic acid	Oleic acid	Linoleic acid	Arachidonic acid
Mucosa	24·7(5·7)	9·3(0·41)	40·4(1·0)	16·9(0·9)	4·2(0·4)
Tumour	22·9(0·6)	11·3(1·0)	38·4(1·2)	15·4(1·1)	11·7(1·5)*

Proportional values of fatty acid content (mean (s e.m.)); * $P=0{\cdot}0025$, Mann–Whitney U test

The modulation of colonic mucosal membrane fatty acid composition by dietary fatty acids may increase the susceptibility of the colon to carcinogen. Arachidonic acid, which is the precursor molecule for prostaglandins, is a possible promoter or co-carcinogen in colorectal cancer.

Recovery from pouchitis: the mechanism of adaptive ileal villus regrowth

W.A. Kmiot, D J. Youngs and M.R.B. Keighley, *The General Hospital, Birmingham, UK*

Reservoir ileitis (pouchitis) is associated with acute diarrhoea which usually responds to metronidazole. To determine whether the severe villus atrophy typical of pouchitis is due to reservoir bacterial overgrowth and whether the mechanism of villus regrowth following treatment involves increased cellular proliferation, we have measured the crypt cell production rate (stathmokinetically), villus configuration and faecal bacteriology in 30 patients: (1) pouchitis ($n=10$), (2) no pouchitis ($n=10$), (3) ileostomy controls ($n=10$). The 20 pouch patients had repeat studies following metronidazole therapy

The crypt cell production rate (CCPR) was significantly higher in the pouchitis group, 2·05 (1·1–2·8)* cells/crypt/h (CCH), than in either the no pouchitis group, 1·0 (0·8–1·8)* CCH, or ileostomy controls, 0·8 (0·35–1·2)* CCH, $H=8{\cdot}517$, $P<0{\cdot}01$**. There was a positive correlation with severity of villus atrophy ($\phi=0{\cdot}68$*** $P<0{\cdot}01$). Following metronidazole treatment CCPR decreased in the pouchitis group from 2·05 (1·1–2·8)* to 0·9 (0·35–1·05)*, $z=3{\cdot}1$, $P<0{\cdot}05$, and the villus atrophy index increased from 1·0 (0·73–1·25)* to 1·8 (1·6–2·04)*, $z=-3{\cdot}78$, $P<0{\cdot}05$, signifying villus regrowth. These changes did not occur in patients with no pouchitis. Aerobic bacterial counts did not differ between the groups. Anaerobic counts were similar between the pouchitis patients, 2×10^8 ($2{\cdot}5\times10^6$–$3{\cdot}8\times10^9$)* CFU/ml, and those with no pouchitis, 4×10^8 ($1{\cdot}25\times10^7$–$5{\cdot}75\times10^9$)* CFU/ml, $z=1{\cdot}2$, n.s., with the ileostomies having significantly fewer counts, 1×10^6 ($2{\cdot}5\times10^5$–1×10^8)* CFU/ml, $H=9{\cdot}793$, $P<0{\cdot}05$**.

This study suggests that bacterial overgrowth is unlikely to be a cause of pouchitis and that the mechanism of adaptive villus regeneration induced by metronidazole involves an increased CCPR

* Median (95 per cent CI), ** analysis of variance, *** Spearman's rank correlation.

Transfusion status and extent of disease as predictors of recurrence of Crohn's disease

A.D. Scott, J.K. Ritchie and R.K.S. Phillips, *St Mark's Hospital, City Road, London, UK*

In order to identify factors of predictive value in assessing the risk of recurrence after resections for Crohn's disease we have analysed the results of right hemicolectomy for terminal ileal or ileocolic disease in 197 patients (105 female and 92 male, mean age 31·1 years, range 15–62 years) operated on between 1947 and 1987. Recurrent disease was diagnosed in 73 (37 per cent) patients, this diagnosis was made radiologically in 52 (71 per cent), histologically in 19 (26 per cent) and endoscopically in two (3 per cent). Of the 73 patients with recurrence 49 (67 per cent) have undergone further surgery at some time. The mean follow-up in the non-recurrent patients is 8 years (range <1–35). Despite its established immunomodulatory effect in renal transplantation and possible importance in cancer surgery, perioperative blood transfusion was not found to be significantly associated with recurrence which occurred in 37·6 per cent of the transfused patients and 36·5 per cent of the non-transfused patients. However, the length of involved bowel as measured by the pathologist was very closely and highly significantly related to the risk of recurrence with a correlation coefficient of 0·955 ($P<0{\cdot}001$)

Pouchitis following restorative proctocolectomy: an evaluation of ^{111}indium-labelled granulocytes for diagnosis

W.A Kmiot, L.K. Harding, S.R. Hesselwood, N. Smith and M.R.B. Keighley, *The General Hospital, Birmingham, UK*

Acute ileal reservoir inflammation (pouchitis) occurs in 5–45 per cent of patients, 80 per cent of whom improve with metronidazole. Diagnosis may be difficult since inflammation has a patchy distribution when assessed by endoscopy or biopsy. We have evaluated ^{111}indium-labelled granulocyte scanning and faecal granulocyte excretion for diagnosis in 27 patients at 24 (18–33) months* following restorative proctocolectomy. Pouchitis on clinical, histological and sigmoidoscopic criteria was present in ten patients. Seven had positive scans and all seven had increased faecal excretion (sensitivity 70 per cent). The remaining 17 patients without pouchitis had 14 negative scans and normal faecal excretion (specificity 82 per cent, positive predictive value (PPV) 66 per cent, negative predictive value (NPV) 94 per cent) In patients with pouchitis and positive scans 1 month of treatment with metronidazole was associated with a significant reduction in the scan activity from a grade of 2 (2–3)* to 1 (0–1)*, $z=2{\cdot}882$, $P<0{\cdot}05$, and of faecal excretion from 7·5 per cent (4–31 per cent)* to 1·35 per cent (0·4–10 per cent)*, $z=1{\cdot}922$, $P<0{\cdot}03$. Metronidazole treatment was associated with a significant reduction in 24 h defaecation frequency from 8 (7–9)* to 5 (4–6)*, $z=2{\cdot}781$, $P<0{\cdot}05$, in sigmoidoscopic grade from 2 (2–3)* to 1 (0–1)*, $z=2{\cdot}882$, $P<0{\cdot}05$, and in the histological score from 4 (3–6)* to 1 (0–2)*, $z=2{\cdot}63$, $P<0{\cdot}05$. No change in these parameters was observed in patients receiving treatment who had negative scans.

This study shows that ^{111}indium granulocyte scanning is a useful method of diagnosis in pouchitis, particularly when inflammation is patchy. It also identifies patients who are likely to improve with metronidazole therapy

* Median (95 per cent CI)

Continuous pouch-anal manometry after restorative proctocolectomy

P.M. Sagar, P.J. Holdsworth and D Johnston, *University Department of Surgery, Leeds General Infirmary, Leeds, UK*

Simultaneous ambulatory anorectal manometry has shown the importance of the sampling reflex for discrimination of rectal contents We have used this technique to study patients after restorative proctocolectomy (RP). Our hypothesis was that this important sampling reflex would be retained when the entire anal canal had been preserved with end-to-end anastomosis (EEA), that is without mucosectomy, but lost in those who had undergone mucosectomy with endoanal anastomosis (EAA)

Pouch and anal canal pressures were measured using a 2 mm diameter microtransducer catheter containing two sensors 6 cm apart. Pressures were recorded for 3 h on a portable microprocessor for subsequent computer analysis. Thirteen controls and 31 patients, 14 with mucosectomy, were studied They were encouraged to continue normal activities during the recordings. Results are shown in the *Table*.

	Control	EEA	EAA
Number of patients	13	14	17
Spontaneous sphincter relaxation	13	13	2
Sampling episodes (median/h)	4	5	0
Recognition of sampling episodes (%)	47	40	30

Spontaneous sphincter relaxation and sampling episodes were significantly reduced after EAA ($P<0{\cdot}01$, Mann–Whitney U test) In contrast, EEA preserves normal discriminatory function of the anal canal, supporting our hypothesis

Changing incidence of human papillomavirus-associated anal cancer, using a new technique for DNA hybridization of fixed tissue

J.H. Scholefield, N.A. Shepherd, P. McIntyre and J.M.A. Northover, *ICRF Colorectal Cancer Unit, St Mark's Hospital, City Road, London, UK*

An association between anal squamous cell carcinoma (SCC) and human papillomavirus (HPV) has been reported[1]. In this country the incidence of benign genital papillomavirus infection has increased markedly over the last 20 years. We have examined a series of anal cancers collected over a 40-year period to look for changes in the incidence of HPV DNA in these tumours.

Existing methods for DNA hybridization of fixed tissue are insensitive and require large amounts of tissue. To overcome this problem we have adapted a technique of DNA preparation from whole cells[2] to examine fixed tissue by DNA hybridization. The age of the tissue specimen did not influence the signal obtained by this technique. This technique has been used to examine 200 tissue specimens from anal SCC.

There has been a threefold increase in the proportion of HPV related anal SCC in the last 10 years when compared with the previous 30 years ($\chi^2=15·6$, $P<0·001$). This parallels the rise in the incidence of HPV infections in the UK and supports the hypothesis that HPV may be an aetiological factor in anal cancer.

The new technique described for the DNA blotting of fixed tissues could be used to screen libraries of tissue for oncogenes in numerous applications.

Is the gastrocolic reflex absent in diverticular disease?

H. Thorburn, J. Goldberg, K. Carter and I.G. Finlay, *Royal Infirmary, Glagow, UK*

Ingestion of food normally stimulates colonic motility Patients with diverticular disease (DD) have symptoms after food, perhaps resulting from an anomalous prandial response. We have developed a novel aerial/computerized analysis system for use with free radiotelemetry pressure capsules. The left colonic motility index (MI), percentage activity, number of peaks >5 mmHg/h and number of peaks >50 mmHg/h were calculated for 1 h before and after meals in 21 patients with diverticular disease (seven mild, eight moderate, six severe disease) and six controls.

The preprandial motility index was 317 (114) in control subjects, increasing to 407 (133) after food. The corresponding values for patients with diverticular disease are shown in the *Table*.

	Mild DD	Moderate DD	Severe DD
Preprandial MI	247 (53)*	516 (114)**	1025 (169)**
Postprandial MI	520 (111)*	658 (132)**	1024 (93)**

* $P<0·05$, ** $P=$ not significant

The number of peaks >50 mmHg/h also increased with severity of DD (4·4(3) mild, 2·4(1) moderate, 15·5(4) severe), $P<0·05$. The corresponding postprandial values were 6·9(4), 7·8(5), 16·5(6).

These data suggest that the gastrocolic reflex is preserved in mild diverticular disease, but is absent in moderate/severe disease.

Portable non-invasive surface electromyography in the assessment of anal physiology: a comparative study

M. Pinho, K. Hosie and M.R.B. Keighley, *Queen Elizabeth Hospital, Birmingham, UK*

Surface electromyography is sometimes considered a non-specific method for assessment of anal sphincter function. However, needle EMG is a painful examination and may therefore give spurious data. Anal manometry is the most common method to study anal functional disorders. We have carried out a prospective study to compare these two methods in order to determine the potential role of surface EMG in the assessment of anal physiology.

Using a specially designed portable unit, intra-anal integrated surface EMG and anal manometry were performed in 44 patients with various anorectal disorders at rest and during maximal voluntary sphincter contraction. Mean values of EMG activity were 37·9 μV (0–150, s.d. 35·4) and 114.9 μV (10–324, s.d. 78·4) and corresponding anal pressures were 93·1 cmH$_2$O (16–160, s.d. 38·9) and 212·8 cmH$_2$O (24–600, s.d. 123·7) at rest and at squeeze, respectively A significant correlation was found between results with both methods at rest ($P<0·001$, $r=0·521$) and squeeze ($P<0·001$, $r=0·791$) (least squares) When correlation between rest and squeezing activity in each isolated method was assessed, a higher correlation coefficient was found with the EMG ($P<0·001$, $r=0·847$) than with anal manometry ($P<0·001$, $r=0·675$).

These results suggest that intra-anal integrated EMG is a useful non-invasive portable method of assessing anal function which is superior to conventional manometry.

EMG biofeedback as a domiciliary treatment of anismus

N.R. Binnie, B.M. Kawimbe, M. Papachrysostomou and A.N. Smith, *Department of Surgery, Western General Hospital, Edinburgh, UK*

Anismus (spastic pelvic floor syndrome) is the inappropriate contraction of the pelvic floor while straining at stool and causes intractable constipation. The non-relaxation of the pelvic floor can be detected using an anal plug surface EMG electrode An electromyographically derived anismus index first compared the EMG activity during defaecation straining with the EMG activity during voluntary squeezing Biofeedback using visual display of the EMG signal was then used as a retraining exercise in 15 subjects (12 women and three men with a mean (s.d.) age of 45 (17) years) with constipation due to anismus. The anismus index pretreatment was 69·5 (28·7) (range from 43 to 160). The subjects were taught biofeedback suppression of the non-relaxing pelvic floor signal in hospital and had twice daily sessions using portable domiciliary biofeedback equipment for 2–4 weeks, the duration of treatment depending on their subjective responses (defaecation time, defaecation difficulty) measured on an analogue scale. The anismus index after biofeedback was 13·7 (16) (range from −25 to 35·7), $P<0·01$ All subjects had subjective improvement in defaecation times and in analogue scores for defaecation difficulty

A new method of limb blood flow measurement applied to diagnostic problems in vascular surgery: is it of value?

D. Wilkinson, J.B.J. Fozard, A. Parkin and R.C. Kester, *St. James's University Hospital, Leeds, UK*

In a patient with suspected claudication the history, signs, and ankle/brachial systolic pressure (Doppler) ratios may be inconsistent, making the diagnosis unclear We have developed a new method of limb blood flow measurement[1]. Normal flow is 11·3–21·6 ml/100 ml of tissue/min and flow to limbs with claudication is 1·8–8·25 ml/100 ml, does this technique help to manage such patients? Twenty-four patients presented as diagnostic problems. Eleven had a convincing history but six of these had palpable pedal pulses, the other five had normal Doppler ratios. Of 13 with a poor history six had absent pulses, and of the other seven with palpable pulses, two had abnormal and five had normal Doppler ratios

n	3	2
Limb blood flow	>8 ml/100 ml/min	<8 ml/100 ml/min
Diagnosis	Osteoarthritis of spine (2) or knee (1)	SFA occlusion (2)

All 24 patients have had blood flow to both legs measured. Twelve had reduced flows consistent with claudication (<8 ml/100 ml of tissue/min) Eight of these have undergone arteriography which demonstrated significant vascular disease, three await arteriography and one had surgery to rheumatoid toes deferred. Of 12 with normal flows three had normal arteriograms, the other nine have been found to have significant orthopaedic problems affecting spine, hips or knees In every case the history, signs or Doppler ratios were potentially misleading but all cases of significant arterial disease were detected by the new technique. It is cheap, readily available and effectively selected cases for referral or arteriography.

Platelet adhesion to human amnion, Dacron and PTFE assessed in vitro

R. Downing, C. Jones and M.R.B. Keighley, *Department of Surgery, University of Birmingham, Birmingham, UK*

Successful clinical application of endothelial cell seeding of arterial prostheses to reduce thrombogenicity may be prevented by lack of suitable autogenous vein from which to harvest cells, variability in cell yields and rejection of cells obtained from cadaveric donors. Human amnion cells are readily available, do not express major histocompatibility antigens and survive after allotransplantation We have assessed the thrombogenicity of human amnion cells by estimation of labelled platelet adherence *in vitro*.

Segments of amnion from elective Caesarean sections, Dacron® (Du Pont) and polytetrafluorethylene (PTFE) were maintained in tissue culture for up to 23 days. Human platelets labelled with ^{111}indium oxine were exposed to the surface of each material for 40 min and removed by gentle washing Thrombogenicity was estimated as the ratio of the radioactivity remaining on the surface of each material after washing to the radioactivity of the initial platelet inoculum expressed as a percentage. Results are given in the *Table*.

	Before culture	After 23 days' culture
Amnion cells	7·0 (2·9)	8·0 (1·6)
Amnion reversed membrane	28·0 (4·9)	36·0 (11·6)
Dacron	67·0 (3·0)	42·0 (16·9)
PTFE	21·6 (3·3)	11·3 (1·2)

Values are mean(s.d.)

These data suggest that amnion cells have low thrombogenic potential and further investigation of their use in seeding arterial prostheses is warranted.

Can we select patients suitable for lumbar sympathectomy?

R.H. Morgan, J.V. Psaila, G. Carolan*, J. Stone, W.T. Davies and J.P. Woodcock*, *Departments of Vascular Surgery and *Medical Bioengineering, University of Wales College of Medicine, Cardiff, UK*

Since not all patients respond favourably to lumbar sympathectomy a predictive test would assist in the management of the critically ischaemic limb. Duplex ultrasound volume flowmetry offers a precise non-invasive method for evaluating blood flow changes to the lower limb. Initially, the change in mean common femoral artery flow after postural change was studied in three groups of patients: normals ($n=12$), claudicants ($n=7$), and patients with rest pain ($n=9$) The mean (s.d.) change in blood flow was −78(116), −112(123), and 131(89) ml/min. Patients with rest pain showed a highly significant increase in common femoral artery flow ($P<0{\cdot}0001$, compared to normals). Claudicants responded significantly differently to normals ($P<0{\cdot}03$).

Eight patients were studied before and after lumbar sympathectomy. Patients with an initial high vasomotor tone exhibited a fall in flow with dependency (normal-type response), and showed a clinical improvement after sympathectomy, which was manifested by a lowered vasomotor tone Patients with an initial low vasomotor tone exhibited a poor symptomatic response to sympathectomy.

In conclusion, normal or mildly ischaemic limbs respond to dependency by a fall in axial artery limb blood flow. In contrast, patients with critical ischaemia and rest pain often show a rise in limb flow after dependency, as did those who underwent sympathectomy. Patients who exhibited a negative orthostatic flow response respond successfully to sympathectomy.

Outflow vascular resistance and early graft occlusion in the lower limb

G.G. Cooper, C. Austin, E. Fitzsimmons, J.M. Hood and A.A.B. Barros D'Sa, *Vascular Surgery Unit, Royal Victoria Hospital, Belfast, UK*

The 'run-off' of arterial bypass grafts may be assessed in terms of vascular resistance (VR). VR has been measured intraoperatively in the outflow artery of femoropopliteal and femorodistal grafts to establish its relationship to graft patency 10 days after surgery.

VR before and after intra-arterial papaverine injection was derived from the relationship between pressure and flow in the popliteal (36), tibial (eight) or peroneal (two) artery while the patient's own blood was infused into it at 74 ml/min. Graft patency or occlusion was determined by ankle pressure measurement, arteriography or re-exploration.

The VR of nine grafts which thrombosed was 1155(346) peripheral resistance units (mPRU), expressed as mean (s.d.), significantly greater than that of 37 patent grafts, 880(328) mPRU ($P=0{\cdot}02$). After papaverine, VR was 844(384) mPRU in thrombosed and 506(217) mPRU in patent grafts ($P=0{\cdot}005$). The VR value which indicated the outcome of bypass grafting most efficiently was 800 mPRU after papaverine This was 87 per cent accurate and had a sensitivity of 67 per cent, a specificity of 92 per cent and a predictive value of 67 per cent for graft thrombosis.

Early graft thrombosis is associated with a high outflow VR. A discriminative value has been defined which has high specificity for early graft thrombosis

Accidental injury causes prolonged suppression of the baroreflex in man

I.D. Anderson, R.A. Little and M.H. Irving, *North Western Injury Research Centre and Department of Surgery, Hope Hospital, Manchester, UK*

Injury causes profound systemic effects and animal studies have shown that these may include an alteration of baroreflex function[1]. The baroreflex controls blood pressure and heart rate, thus playing a crucial role in acute cardiovascular homoeostasis.

Baroreflex function[2] was studied sequentially in 21 stable, moderately injured patients (injury severity score 9–17) and in 22 controls. Control baroreflex sensitivity was 3·70 (0·09–15·46) ms mmHg^{-1}, median (range). Compared with controls, marked baroreflex suppression was demonstrated within 4 h of injury (1·13 (−0·6–6·78) ms mmHg^{-1}, $P<0{\cdot}05$ using the Wilcoxon rank sum test), at 3 days after injury (1·36 (−0·1–2·77) ms mmHg^{-1}, $P<0{\cdot}001$ using the Wilcoxon rank sum test) and even 2 weeks after injury (2·57 (−0·08–6·52) ms mmHg^{-1}, $P<0{\cdot}05$ using the Wilcoxon rank sum test). Paired testing showed that partial recovery of baroreflex function occurred between 3 and 14 days after injury ($P<0{\cdot}01$ using the Wilcoxon signed rank test) Five months after injury, injured patients were indistinguishable from controls

Following injury, resting heart rate and blood pressure were elevated and sinus arrhythmia was reduced, with a time course similar to that of baroreflex suppression.

The arterial baroreflex is suppressed within 4 h of injury and remains so for 2 weeks. During this time the normal relationship between heart rate and blood pressure is lost. These changes in this important cardiovascular homeostatic reflex have clinical implications

1 Redfern WS, Little RA, Stoner HB, Marshall HW. Effect of limb ischaemia on blood pressure and the blood pressure heart rate reflex in the rat. *Q J Exp Physiol* 1984, **69**: 763–79.

Reduced immune, haemostatic and cardiac function and increased postoperative stress-response may mediate increased postoperative morbidity in asymptomatic alcoholics

H. Tonnesen, K.R. Pedersen, L. Hojgaard, K.H. Stockholm, K. Klarlund, H.-J. Nielsen and H. Kehlet (introduced by H.J.G. Burns), *Department of Gastric Surgery, Hvidovre Hospital, DK-2650 Hvidovre, Denmark*

Postoperative morbidity in alcoholics is increased[1,2]. To investigate possible mechanisms 14 asymptomatic alcoholics (≥60 g alcohol/day) undergoing elective colorectal resection were matched (sex, nutrition, age, weight, cardiovascular and pulmonary disease, diagnosis and surgery) to 14 controls (<25 g alcohol/day) in a prospective study. The following results were obtained (mean (s.e.m.), *$P<0{\cdot}05$, **$P<0{\cdot}01$, Mann–Whitney U test)

The preoperatively prolonged bleeding time in the alcohol group (AG), 3·4(0·3) min compared to the controls (CG) 2·1(0·2)**, continued on days 1 and 7 after surgery, 3·1(0·3) *versus* 1·9(0·3)**

Preoperatively, the ejection fraction (cardioscintigraphy) was reduced in the AG, 56(2) per cent compared to 69(2)**

Preoperatively, the AG had reduced delayed hypersensitivity (skin test response 56(1) mm^2 *versus* 110(19)**) and NK cell activity (18(4) per cent *versus* 46(4)** The postoperative day 1 suppression of NK cell activity was most pronounced in the AG, 7(1) per cent *versus* 29(7)** (day 1) and 14(3) per cent *versus* 27(6)* (day 7)

The AG's stress-response (cortisol) was higher 24 h postoperatively compared to the CG*.

Sixty-four per cent of the AG had postoperative complications (bleeding, cardiopulmonary, infectious) compared to 14 per cent in the CG** (χ^2 test).

Our results suggest that increased postoperative morbidity in alcoholics may be due to decreased haemostatic function, subclinical cardiac insufficiency, pre- and postoperative immunodepression and increased surgical stress-response.

Reversal of supersensitivity in intimal hyperplastic rabbit aorta exposed to hypercholesterolaemia

P.D. Carey, M.K. O'Malley and H.F. Given, *Department of Surgery, Regional Hospital and University College, Galway, Ireland.*

Vascular endothelial denudation results in intimal hyperplasia which is associated with increased sensitivity and increased maximal contraction in rabbit aorta in response to noradrenaline. The aim of this study was to characterize the effect of hypercholesterolaemia on contractility following endothelial denudation. Rabbit abdominal aorta was denuded using a balloon catheter ($n=14$) and significant intimal hyperplasia developed by 2 weeks. The rabbits were then fed an atherogenic diet containing 2 per cent cholesterol and were killed 1, 4 and 8 weeks thereafter. Isometric contraction in strips of denuded and non-traumatized (control) aorta was measured in an organ bath in response to cumulative doses of noradrenaline or histamine. Dose–response curves were constructed and compared at the 50 per cent maximal contraction level (EC_{50}). Results are given in the *Table*

Cholesterol	Control (EC_{50})	Denuded aorta (EC_{50})
1 week, $n=5$	6·80 ($1{\cdot}82\times10^{-6}$)	1·60 ($1{\cdot}46\times10^{-7}$) $P<0{\cdot}01$
4 weeks, $n=5$	6·67 ($1{\cdot}81\times10^{-6}$)	0·90 ($0{\cdot}50\times10^{-6}$) $P<0{\cdot}02$
8 weeks, $n=4$	5·27 ($2{\cdot}34\times10^{-6}$)	1·23 ($0{\cdot}89\times10^{-5}$) n s.

Molar concentration of noradrenaline, mean (s e.m.), Student's *t* test

These results confirm the previously demonstrated supersensitivity in intimal hyperplastic rabbit aorta to noradrenaline There was an increase to 171·4(23·7) per cent, mean (s.e.m.), in maximal contraction in atherosclerotic vessels in response to histamine. These data demonstrate that the increased contractile response to noradrenaline is reversed with the development of atherosclerosis and that it is replaced by increased histamine contractility.

Pulmonary platelet sequestration during major surgery

D.B. Hocken, D.A.J. Galvin, R.A. Harper, D.T. Parry and C.N. McCollum, *Department of Surgery, Charing Cross and Westminster Medical School, London, UK*

Pulmonary dysfunction frequently occurs following major surgery and may be related to platelet microembolization. The influence of prostaglandin E_1 (PGE_1), a potent inhibitor of platelet activation, which improves perioperative pulmonary haemodynamics[1] was studied in 24 pigs during experimental surgery.

Autologous ^{111}indium-labelled platelets were injected 24 h prior to standardized surgery. *In vivo* ^{111}In-labelled platelet uptake in both lungs was measured with a highly collimated sodium iodide probe and ratemeter and expressed as a ratio to the reference area (head). Serial platelet count and pulmonary function were also recorded.

Pulmonary platelet uptake in controls rose from a mean of 3·68(1·02) at the start of surgery to 5·95(0·84) during surgery and 7·64(2·8) on the third postoperative day, and from 3·53(0·68) to 5·17(1·06) and 5·56(0·97) on PGE_1, a significantly greater rise ($P<0{\cdot}01$ Mann–Whitney *U* test) in controls The fall in platelet count was reduced from 163×10^9/l to only 72×10^9/l on PGE_1 ($P<0{\cdot}02$).

Alveolar–arterial oxygen difference (AaD_{O2}), an index of injury to the alveolar–capillary membrane, showed a very similar pattern to pulmonary platelet uptake rising to 27·35(3·63) mmHg in controls, compared with only 14·86(1·39) mmHg on PGE_1 ($P<0{\cdot}02$).

PGE_1 inhibited platelet consumption and the subsequent pulmonary sequestration of ^{111}In-labelled platelets which correlated with an improvement in postoperative pulmonary function

1 Hocken DB, Galvin DAJ, McCollum CN. The influence of prostaglandin E_1 on pulmonary and systemic haemodynamics during aortic surgery. *Eur J Vasc Surg* 1989; 3: 1–6.

Comparative study of 24 h ambulatory oesophageal pH in patients with erosive oesophagitis treated by cimetidine and omeprazole

T.C.B. Dehn and M.G.W. Kettlewell, *Department of Surgery, John Radcliffe Hospital, Oxford, UK*

The effect of treatment of erosive oesophagitis by cimetidine (CIM) and omeprazole (OM) has been studied by 24 hour ambulatory oesophageal pH (24 h pH). Eighteen patients with endoscopic erosive oesophagitis were randomly allocated to receive 8 weeks of treatment, CIM 400 mg q.d.s. or OM 40 mg o.d. Ambulatory 24 h pH measurements were undertaken before and after 29 days of therapy Results of distal oesophageal acid exposure (<pH 4) are shown in the *Table* Endoscopic healing occurred in five CIM and six OM patients. Median total percentage <pH 4 were 5·9 (2·4–16·4) and 0·05 (0–0·1), respectively ($P=0{\cdot}0001$). Median percentage time <pH 4 in four CIM and three OM patients without endoscopic healing was 16·6 (7·5–36) and 10 (1·1–23), respectively. Before treatment reflux episodes/24 h were 35 (32–81) for CIM and 20 (9–65) for OM (P=n.s.). At day 29 these were 30 (4–61) CIM and 1·0–38 OM ($P=0{\cdot}001$). Before treatment the longest reflux episode (min) was 6 (2–40) CIM and 8 (1–58) OM, at day 29 these were 16 (0–33) CIM and 0 (0–10) OM ($P=0{\cdot}100$).

OM is more effective than CIM in reducing all parameters of gastro-oesophageal acid reflux.

Median percentage time for oesophagus <pH 4 (* $P=0{\cdot}0001$)

		Day time		Night time		Total	
	n	Day 0	Day 29	Day 0	Day 29	Day 0	Day 29
Cimetidine	9	10·48	10·25	7·66	11·56	9·51	10·78
Omeprazole	9	11·25	0·74*	11·31	7·10	11·43	3·37

Role of surgery in preventing reflux and complications in Barrett's metaplasia

G.P. McEntee, T.F. Gorey, R.C. Stuart, N. Nolan, P.J Byrne, P. Lawlor and T.P.J. Hennessy, *Department of Surgery, St. James's Hospital, Dublin, Ireland*

The presence of Barrett's metaplasia is a controversial indication for antireflux surgery[1] We comared the results of surgery and medical therapy in two groups of 20 patients with histologically proven Barrett's mucosa presenting during the 10 years from 1979, with mean follow-up of 3·4 years. Initial lower oesophageal sphincter pressures (LOSP) and pH profiles were comparable in both groups. The results are shown in the *Table*

	Surgical treatment ($n=20$)		Medical treatment ($n=20$)	
	Preoperative	Postoperative	Prereflux	Postreflux
Percentage time pH<4 median (range)	31·9(5·7–77)	0·5(0–41)	22·2(5·1–73·9)	13·6(0·3–79)
	$P<0{\cdot}01$		P=n s	
LOSP (mmHg) mean (s.e m)	10·04(0·8)	16·2(1·9)	11·5(2·02)	14·7(4·3)
	$P<0{\cdot}05$		P=n s	
Stricture/ ulceration	10	0	12	5
		$P<0{\cdot}05$		

Dysplasia regressed in four patients and progressed in one after surgery, while none regressed but four progressed after medical therapy Surgery provided better control of reflux, improved sphincter tone, reduced complications and resulted in improved grade of dysplasia.

Non-invasive detection of the gastric migrating motor complex by surface vibration analysis

B. Waldron, P.T. Cullen, B.E. Storey and F.C. Campbell, *Departments of Surgery and Physics, Ninewells Hospital and Medical School, Dundee, UK*

The migrating motor complex (MMC) is the key to gastrointestinal motility disorders, but conventional methods which address this parameter are invasive

In this study, a new computerized non-invasive test called surface vibration analysis (SVA) was evaluated against conventional manometry, for detection of the MMC in ten volunteers. Synchronous studies were carried out at 4 h intervals, first in the fasting phase, then again after acaloric liquid (350 ml isotonic lactulose) in all subjects.

In the fasting phase, SVA detected the gastric MMC in 7/10 volunteers, with a response which was proportional to intragastric pressure change. After liquid, fasting motility patterns persisted in eight volunteers and SVA detected the gastric MMC in all. Liquid enhanced the SVA response to the MMC, but had no effect on intragastric pressure ($\bar{x}$ (s.e.m.) = 40·64 (3·17) mmHg before; 39·3 (3·54) mmHg after liquid). SVA did not detect small bowel MMCs, which had low contractile pressures ($\bar{x}$ (s.e.m.) = 17·6 (3·5) mmHg).

SVA is a non-invasive test which can detect the gastric MMC. Two factors which determine the SVA response have been identified, i.e. contractile amplitude and intraluminal content.

Intestinal cytokinetics during the induction of chronic duodenal ulcer

R.H.K. Gompertz, R.A. Goodlad, N.A. Wright, A. Michalowski*, J.H. Baron and R.C.N. Williamson, *Departments of Surgery and Histopathology RPMS and *MRC Cyclotron Unit, Hammersmith Hospital, London, UK*

Chronic duodenal ulcer can be induced in mice as an indirect effect of lower mediastinal irradiation, the resulting ulcers closely resembling those seen in man. Using a stathmokinetic technique we have studied crypt cell production rate (CCPR) in 72 female CFLP mice weighing 25–40 g randomly allocated to three groups. Controls were anaesthetized only.

Irradiated animals received a single dose of 18 Gy 250 kV X rays to either the upper mediastinum (which never causes ulceration, irradiated control) or to the lower mediastinum (which induces ulcers in 45 per cent in 7 days, ulcer group). Studies were performed at days 3 and 7 postirradiation. Animals were killed at intervals from 30 to 180 min after vincristine (1 mg/kg IP) and the duodenum and small bowel were immediately removed and fixed before counting. The number of cells arrested in metaphase in 20 well oriented crypts per sample were plotted against time to give CCPR in cells/crypt/h (mean(s.e.m.)).

		Duodenum	Ileum
Day 3	Control	7·5 (2·85)	14·34 (2·7)
	Irradiated control	12·72 (3·42)	18·48 (2·0)
	Ulcer group	26·52* (2·52)	25·0 (4·7)
Day 7	Control	9·9 (3·42)	6·84 (1·56)
	Irradiated control	6·96 (2·64)	8·7 (2·7)
	Ulcer group	5·52 (2·58)	5·52 (1·56)

* $P < 0·01$

Duodenal CCPR trebled during ulcer induction but returned to normal by the time ulceration occurred. Cellular changes associated with ulceration may thus be demonstrable only in the induction phase rather than in the established ulcer. Further studies during this period may be central in understanding the mechanisms of chronicity in duodenal ulcer.

Non ulcer dyspepsia: a hypomotility disorder?

B. Waldron, P.T. Cullen, D. Hopwood, D. Sutton, N. Kennedy and F.C. Campbell, *Departments of Surgery and Medical Physics, Ninewells Hospital and Medical School, Dundee, UK*

Non ulcer dyspepsia (NUD) is a common gastroenterological diagnosis with obscure aetiology. In this prospective study, 40 symptomatic patients were diagnosed as NUD, after exclusion of peptic ulcer, gallstones and oesophageal reflux by endoscopy, ultrasound and 24 h pH monitoring, respectively. Gastric and small bowel function were investigated by measurement of six objective parameters in all patients: gastric emptying (GE), oral to caecal transit time (OCTT), antral campylobacter (CpB), small bowel bacterial overgrowth (SBBO), peak acid output (PAO), and enterogastric bile reflux (EGBR). All tests were validated in 20 healthy controls and abnormalities were defined as more than two standard deviations outwith the mean.

	GE (Delay)	OCTT (Delay)	CpB (+)	SBBO (+)	PAO (High)	EGBR (+)
Number of patients	23	11	16	8	2	1
Percentage of total (%)	58	28	40	20	5	2

In total 29/40 patients had hypomotility, with delayed GE and/or prolonged OCTT. All cases of bacterial overgrowth were associated with hypomotility.

In conclusion, hypomotility is common in NUD, is often accompanied by bacterial overgrowth, and may be implicated in aetiology

Human gastric tissue oxygenation and the effect of truncal vagotomy

W.G. Sheridan, R.H. Lowndes and H.L. Young, *University Department of Surgery, University Hospital of Wales, Cardiff, UK*

Non-uniform distribution of blood flow in the stomach has been demonstrated in previous studies and relative ischaemia has been implicated in the pathogenesis of peptic ulceration. In addition, vagotomy has been shown to decrease gastric blood flow. This study uses preoperative tissue oximetry to evaluate tissue oxygenation in the human stomach, of which little was previously known, and examines the effect of truncal vagotomy.

Using a Clark polarographic oxygen electrode with a linear response to oxygen ($r = 0·998$, $P < 0·001$), detailed 'mapping' of tissue oxygen tension levels (P_{tO_2}) on the anterior surface of the stomach was carried out in five patients. Although no significant difference in mean P_{tO_2} was detectable between greater and lesser curvatures of the stomach at any level, there was a significant difference in mean P_{tO_2} levels between the body and antrum (Mann–Whitney U test, $P < 0·01$).

The effect of truncal vagotomy on gastrointestinal P_{tO_2} was evaluated in six patients undergoing this procedure for duodenal ulceration. Mean postvagotomy stomach P_{tO_2} levels (46 (12) mmHg) were significantly lower (Wilcoxon test, $P < 0·001$) than prevagotomy levels (59 (14) mmHg).

This work provides the first objective evidence of relatively diminished tissue oxygenation in the ulcer bearing area of the stomach and confirms blood flow studies of the effects of vagotomy

Proximal highly selective vagotomy: an operation for type I gastric ulcer when fibrosis limits dissection of distal lesser curve

G. Martin, K.S. Naik, R.C. Macdonald, W.A.F. McAdam and D. Johnston, *University Department of Surgery, The General Infirmary at Leeds and Airedale District General Hospital, UK*

Compared with Billroth I PG, highly selective vagotomy with ulcer excision (HSVE) was shown in the Sheffield trial to yield much better functional results in gastric ulcer (GU) patients, while recurrence rates were similar[1]. However, fibrosis along the lesser curve can render the procedure difficult to perform. Our hypothesis, based on the work of Oi[2], was that a vagotomy proximal to the ulcer might prove sufficient

Of 109 GU patients, 24 were treated by proximal HSVE and 85 by HSVE between 1970 and 1988. Median PAO^{Pg} was 15·3 mmol/h (upper quartile 18·6, lower quartile 10·35, $n = 13$) and 21·3 (UQ 27·9, LQ 15·12, $n = 47$) respectively before operation, and median reductions 1 week after operation, 79 per cent and 65 per cent, respectively. None of the insulin tests were positive after proximal HSVE three (7 per cent) were positive after HSVE. Recurrent ulceration developed in ten patients (12·9 per cent by life table analysis): two after proximal HSVE and eight after HSVE (n.s.): 84 per cent of patients were in Visick grades I + II after proximal HSVE and 82 per cent after HSVE (n.s.)

When fibrosis along the lesser curve limits dissection, vagotomy round the oesophagus and down the lesser curve as far as the ulcer denervates the parietal cells efficiently and yields good clinical results

Vagotomy and ranitidine prevent the postprandial reduction in urine acid output

A. Rai and C.D. Johnson, *Department of Surgery, Southampton General Hospital, Southampton, UK*

Changes in urine acidity after a meal correlate inversely with gastric secretory capacity[1]. We investigated this response in patients after vagotomy and in normal volunteers.

In 16 volunteers, gastric peak acid output (PAO) after sham feeding (SF) was median 13 mmol/h, range 7·6 to 17. Sixteen patients had complete vagotomy (PAO to SF <7 mmol/h), and three with recurrent ulcer had an incomplete vagotomy (PAO >7 mmol/h).

Urine acid output in volunteers fell in the 2 h after a meal from basal values by a median −2·2 mmol/h (range −0·4 to −3·1). In seven volunteers given ranitidine 150 mg every 12 h (three doses) before the meal, the change in urine acid output was abolished (median +1·1 mmol/h, range +0·6 to 2·9). Complete vagotomy also abolished the normal postprandial response (median +1·3 mmol/h, range +6·7 to −0·3). In contrast, patients with incomplete vagotomy showed a postprandial fall in urine acid output (range −0·9 to −1·8 mmol/h).

This study shows that changes in urine acid output after food can separate normal volunteers from those given ranitidine and from patients with complete vagotomy. Incomplete vagotomy can be detected by failure to inhibit the normal reduction in urinary acid output.

Does gallstone clearance require both extracorporeal shock wave lithotripsy and chemical dissolution? A randomized study

A. Darzi, A. Leahy, P. Redmond, J.R.T. Monson, C. O'Morain, W.A. Tanner and F.B.V. Keane, *Departments of Surgery and Gastroenterology, Meath and Adelaide Hospitals and Trinity College, Dublin, Ireland*

Following extracorporeal shock wave lithotripsy (ESWL), it is not known whether fragments can be cleared from the gallbladder without the use of oral dissolution therapy (DT). To prospectively assess the efficacy of ESWL and DT, used alone or in combination, we randomized 31 patients to one of three treatment groups: ESWL alone, DT alone or ESWL and DT. All patients had symptomatic gallstones and functioning gallbladders, and the stone profiles were comparable in each group. ESWL was administered using a piezo-electric lithotriptor (EDAP LT-01), and DT consisted of combined bile salt and terpene administration. Clearance was assessed using a combination of ultrasound and oral cholecystography. Each patient was followed up for 6 months and those with less than 50 per cent clearance at the end of 6 months were considered failures.

		Clearance		
Group	*n*	Total	Partial (>50%)	Failures
ESWL	11	0	0	11
DT	10	1	1	8
ESWL+DT	10	5	2	3

The number of patients with total or partial clearance in the ESWL+DT group was significantly greater than those in either DT ($P<0{\cdot}02$ using a χ^2 test) or ESWL alone ($P<0{\cdot}05$). ESWL merely fragments gallstones, and DT is essential to achieve fragment clearance. This study demonstrates for the first time that gallstone clearance following ESWL appears to be DT dependent, and combination of the two modalities is more potent than DT alone.

Does selective peroperative cholangiography result in missed common bile duct stones?

M.S.C. Murison, P.C. Gartell and F.P. McGinn, *Department of General Surgery, Southampton University Hospital, Southampton, UK*

A prospective randomized trial was undertaken to determine if selective peroperative cholangiography resulted in greater morbidity and mortality from missed common bile duct stones. Two hundred and eighty-five patients without indications for common bile duct exploration were randomized blindly into two groups. Group 1 underwent peroperative cholangiography and group 2 did not.

All patients were sent a questionnaire at least 3 years after surgery and 218 of those still living responded (80 per cent). One hundred and thirty-two (60·6 per cent) had peroperative cholangiography. There had been 11 deaths from unrelated causes.

The results showed that routine peroperative cholangiography revealed an unsuspected common bile duct calculus in 12·1 per cent of patients. None of group 2 presented with retained common bile duct stones.

No difference between the two groups was found for postoperative dietary habit, dyspepsia, pain, flatulence, diarrhoea, pale stool or dark urine. One patient in group 1 had endoscopic removal of a retained common bile duct calculus 16 months after cholecystectomy.

It is concluded that peroperative cholangiography does not influence morbidity and mortality from cholecystectomy in selected cases and may be omitted in the absence of clinical indications for common bile duct exploration.

Minimal surgery for symptomatic gallstones: a safe, new procedure in high risk patients

A.L. Leahy, A.W. Darzi, S. O'Gorman, S. Hamilton, W.A. Tanner and F.B. Keane, *Departments of Surgery and Radiology, Meath Hospital, Dublin, Ireland*

Cholecystectomy is associated with a mortality rate of up to 10 per cent in elderly patients. To reduce risk, a combined radiological and endoscopic procedure was introduced. Patients over 60 years old who were considered at high risk were selected for this study. The gallbladder was identified using B-mode ultrasonography, and cholecystotomy was performed under local anaesthesia through a 3 cm incision. A specially designed catheter was introduced into the gallbladder through which endoscopic ultrasonic contact lithotripsy was performed. At operation stone clearance was confirmed endoscopically and using completion cholecystography. Catheter drainage was continued for 7 days until a further cholecystogram confirmed clearance. The procedure was attempted in 13 patients (mean age 72 years) with symptomatic gallstones, all had concomitant cardiovascular or malignant disease.

Successful removal of all stones, under local anaesthesia was possible in 12 patients at the original procedure. In one patient the gallbladder could not be isolated through a mini-incision and formal cholecystectomy was performed under general anaesthesia. The procedures were well tolerated, and cholecystography at 7 days confirmed complete stone clearance in all. Apart from two patients who had persistent bile leaks for 30 and 65 days after catheter removal, there were no other complications. All patients are symptom free at a mean follow-up of 15 weeks, with no recurrent stones.

The new technique of sonographically guided mini-cholecystotomy and endoscopic lithotripsy allows effective treatment of gallstones under local anaesthesia, as a short-stay procedure. A specially designed retention catheter facilitates this procedure, by preventing peritoneal spillage, and by fixing the gallbladder fundus to the anterior abdominal wall.

The development and reversibility of T lymphocyte dysfunction in experimental biliary obstruction

R.L.E. Thompson, T. Diamond, M. Hoper and B.J. Rowlands, *Department of Surgery, The Queens's University of Belfast, Belfast, UK*

Patients with obstructive jaundice have a high incidence of infective complications following surgery. This may be related to changes in cell-mediated immunity. We have studied the effect of experimental biliary obstruction and biliary drainage on immune function. Cell-mediated immunity was assessed by a phytohaemagglutinin stimulation test of splenic lymphocytes. All experiments used adult female Wistar rats.

Group I animals had bile duct ligation (BDL) performed and were killed at 7 day intervals up to 35 days.

Group II animals had BDL for 21 days followed by periods of internal biliary drainage (ID) up to 28 days.

Group III animals had biliary obstruction followed by external biliary drainage (ED) for 14 days. Results are given in the *Table*

Animal group	n	Scintillation	Animal group	n	Scintillation
1 Control	10	27 193 10 027	II 7d ID	10	12 974 3 101*
Sham	10	20 806 7 584	14d ID	9	21 748 2 809
7d BDL	10	25 797 9 284	28d ID	10	34 110 10 346
14d BDL	10	14 744 7 042*			
21d BDL	10	10 927 5 880*	III 14d ED	9	15 014 2 879**
35d BDL	10	7 415 5 172*			

Mean scintillation, 95 per cent confidence limits, * P0 05 compared with controls t test, ** P0·05 compared with 14d ID t test

All the BDL groups had elevation of bilirubin and both ID and ED groups had return of bilirubin to within the normal range. The results demonstrate that depression of cell-mediated immunity in biliary obstruction is progressive, with significant depression after 14 days. This is restored by 14 days ID but not 14 days ED. This may explain why preoperative external biliary drainage does not reduce the incidence of infection in jaundiced patients.

Effect of CCK-PZ and secretin on pancreatic enzyme concentration and severity of experimental pancreatitis in cats

R.I. Hall, J.I. Wyatt, R. Karkera and K.R. Wedgwood, *University Department of Surgery, St. James's University Hospital, Leeds, UK*

Pancreatitis occasionally complicates endoscopic retrograde cholangiopancreatography (ERCP). If pancreatitis is due to endogenous enzyme release its severity could be limited by prior reduction of pancreatic enzyme concentration.

Cats were pretreated with intravenous cholecystokinin-pancreozymin (CCK-PZ) and secretin. Controls received saline Pancreatic enzyme concentration was then determined. Oedematous pancreatitis was induced in six pretreated (group A) and six control cats (group B) by bile salt and enterokinase pancreatic duct perfusion Haemorrhagic pancreatitis was induced in five pretreated (group C) and five control cats (group D) by duct perfusion plus intravenous prostaglandin E_2. Histological severity of pancreatitis and residual exocrine function were measured after 24 hours.

Pretreatment reduced pancreatic enzyme concentration from 125 926 (16 306) U/g to 76 483 (9614) U/g for amylase ($P < 0 05$), 658 121 (15 327) U/g to 433 775 (75 435) U/g for lipase (n.s) and 8261 (1479) µ/g to 6288 (565) U/g for trypsinogen (n.s.). Pretreatment had no effect on histological pancreatitis score: 11 (3–54) for group A, 10 (2–29) for group B, 30 (24–41) for group C, and 33 (9–41) for group D. Residual exocrine pancreatic function was also unaffected by pretreatment.

The severity of haemorrhagic pancreatitis correlated with pancreatic lipase concentration ($r = 0 66, P < 0 05$) but not amylase or trypsinogen.

Pretreatment with CCK-PZ and secretin is unlikely to protect patients from post-ERCP pancreatitis Specific reduction of lipase concentration may be more effective.

Does CT angiography predict the clinical course of pancreatic necrosis?

D.J. Alexander, A. Chalmers, W. Stephenson, K. Wedgwood and M.J. McMahon, *Department of Surgery and Radiology, Leeds General Infirmary, Leeds, UK*

In patients with severe acute pancreatitis computed tomography (CT) angiography indicates the extent of pancreatic and peripancreatic ischaemia, but its prognostic value remains unclear. A weighted scoring system which quantifies the extent of pancreatic and peripancreatic necrosis visualized by CT angiography was compared with clinical outcome in 27 patients with severe acute pancreatitis and a collection containing ischaemic tissue >5 cm diameter. CT angiography was carried out from 2 to 42 days from the commencement of pancreatitis and was scored by 2 radiologists Ten patients had a pancreatic abscess (pus was the dominant element in the collection) and 17 had pancreatic necrosis (necrotic tissue the dominant element). Six patients died and 19 received urgent intervention (surgery in 12 and percutaneous drainage in seven).

Outcome	Score (range and median)		Outcome	Score (range and median)	
Survived	1–12 (6)	$> P < 0 04$*	No intervention	4–9 (6)	> n s *
Died	5–11 (10)		Needed intervention	1–12 (8)	

* Mann–Whitney U test

Thirteen patients who needed intervention scored >6, compared with 2 (25 per cent) of patients who did not receive intervention. CT angiography enables selection of patients with pancreatic necrosis who are at high risk of a deteriorating course, but factors other than the extent or site of necrosis are important to outcome

Beneficial effects of taurolidine in experimental pancreatitis

H.P. Redmond, A.L. Leahy, J. Carey, A. Darzi, P. Marks, F.B.V. Keane and W.A. Tanner, *Department of Surgery, Meath Hospital, Dublin, Ireland*

Taurolidine, a derivative of formaldehyde and the amino acid taurine, has potent antiendotoxin and antimicrobial effects *in vitro* This study assessed the effect of taurolidine in a well-described model of acute pancreatitis.

Sixty four male Wistar rats (250 g) were studied Pancreatitis was induced by intraductal administration of 50 µl of a 4 per cent sodium taurocholate solution at a pressure of 25 cm of water. Taurolidine (100 mg/kg) or saline was administered intravenously immediately following pancreatitis Animals were randomly allocated to group A, sham operated controls; group B, i.v. taurolidine administration; group C, pancreatitis and i.v taurolidine administration; and group D, pancreatitis and i v. saline administration Serum amylase levels and septicaemia on blood culture (BC) were assessed at 4 h Survival was documented at 1 week. Data were analysed by χ^2 and Student's t test.

Group	n	Mean amylase (IU/l)	BC positive	Survival
A sham	5	3 715	0	5
B taur	5	3 636	0	5
C pancr + taur	19	7 040	0	18*
D pancr + saline	35	12 525	20%	5

* $P < 0 001$ for C *versus* D

There was no significant difference in serum amylase levels between all groups. Taulonidine administration after bile salt induced pancreatitis significantly improved survival These data suggest that taurolidine may have a therapeutic role in acute pancreatitis.

A multicentre controlled clinical trial of high volume fresh frozen plasma therapy in prognostically severe acute pancreatitis

T. Leese, C. Hall, M. Holliday, M. Watkins, J.P. Neoptolemos, M. Thomas and A. Attard, *Department of Surgery, University of Leicester, Leicester, UK*

Fresh frozen plasma (FFP) therapy may improve survival in acute pancreatitis The proposed mechanism is the replenishment of specific proteins, particularly α_2 macroglobulin (A_2M), a centrally important antiprotease.

In a multicentre trial, patients with prognostically severe pancreatitis (three or more adverse Glasgow prognostic criteria) are randomized to receive 24 units of FFP or a similar volume of human albumin solution (colloid control) during the first 72 hours. Antiproteases and other proteins are measured on days 1, 3 and 7.

To date 265 patients with pancreatitis have been referred of which 55 with prognostically severe disease were randomized. There were seven deaths in the colloid control group (29 per cent) and four in the FFP group (15 per cent). The concentrations of proteins showing a positive acute phase response (C-reactive protein, α_1 antiprotease α_1 antichymotrypsin, fibrin degradation products, D-dimer) were not influenced by FFP therapy. The exception was plasma fibrinogen, concentrations of which were higher on day 3 in the FFP group ($P < 0·02$). The concentrations of proteins which showed a negative acute phase response (A_2M, antithrombin III, fibronectin) were increased by FFP therapy so that on day 3 concentrations were higher in the FFP group ($P < 0 001$, $< 0 01$, $< 0·05$).

The confirmation that FFP therapy supplements declining concentrations of negative acute phase proteins including A_2M may be important. The trial will continue to see if significant benefit results.

Photodynamic therapy for malignant dysphagia

J.T. Allardice, M.F. Grahn, L. Ilincic, C.P. Swain and N.S. Williams, *The Surgical Unit and Academic Department of Gastroenterology, The London Hospital, Whitechapel, London, UK*

Photodynamic therapy (PTD) is an exciting method of selectively treating carcinoma using a photosensitizing drug (haematoporphyrin derivative (HpD)) activated by laser light. Previous attempts to treat oesophageal lesions have been hampered by failure to deliver light uniformly. We have designed a new light delivery system which overcomes this and have assessed its effect in eight patients (age 25–70, nine treatments) with inoperable malignant dysphagia. Our system uses a polytetrafluoroethylene diffuser on an optical fibre to scatter light cylindrically. A modified Eder–Puestow dilator with a perspex window surrounds this so that circumferential tumours receive uniform light energy density plus or minus 10 per cent. HpD (4–5 mg/kg) was given intravenously 48 h before light delivery (50–150 J/cm², 630 nm light). Assessment before and after treatment was by dysphagia score (0–5) and minimum diameter on quantitative barium examinations:

	Dysphagia score (n=9)		Diam (mm) (n=6)	
	Before	After	Before	After
Median	*3	*5	*3·5	*10·5
Range	0–4	1–5	2·6–5	4·9–15

* Wilcoxon test, $P>0·01$

All patients except one improved their score, maintaining it until death (3 days to 9 months later), with total relief of dysphagia in five. One patient was perforated by instrumentation 4 days after PDT and subsequently died. There were no other complications. One patient has had a complete remission of microscopic tumour recurrence.

Instrumentation of the stricture should be avoided soon after PDT. Using this light delivery system we have demonstrated that PDT is a useful palliative treatment.

Nucleolar organizer region scores in surveillance of Barrett's metaplasia

R.C. Stuart, T.F. Gorey, N. Nolan, P. Gillen, E. Jones, P.J. Byrne and T.P.J. Hennessy, *Departments of Surgery and Pathology, St James's Hospital, Dublin 8, Ireland*

While the risk of carcinoma of the oesophagus in patients with Barrett's oesophagus is low, endoscopic surveillance is advocated. To identify at-risk patients this study assesses the role of nucleolar organizer region (NOR) activity. NORs, which are loops of DNA encoded for ribosomal RNA, have been related to mitotic rate and are identified by means of an argyrophilic histological technique.

Eighty-three tissue sections from 35 patients with Barrett's mucosa were studied in the following groups: (i) metaplasia ($n=25$), (ii) dysplasia ($n=44$, mild 19, moderate 17, severe 8); and (iii) adenocarcinoma ($n=14$). The sections were randomized, coded and NOR activity was scored by two independent observers. The results are shown in the *Table*.

		Dysplasia			
	Metaplasia	Mild	Moderate	Severe	Carcinoma
Barrett's oesophagus ($n=21$)	5·3 (1·2)	6·9 (1·7)	7·8 (1·9)	8·1 (0·9)	
Barrett's epithelium + carcinoma ($n=14$)	5·5 (0·9)	7·2 (0·6)	7·9 (1·7)	11·5 (3·7)	13·9 (5·1)
All cases ($n=35$)	5·3 (1·2)***	7·0 (1·5)**	7·9 (1·8)**	10·2 (3·3)	13·9 (5·1)***

** $P<0·001$ *versus* severe dysplasia; *** $P<0·001$ *versus* all groups

The NOR score correlated well with the histological grading of dysplasia. The NOR score was significantly higher in patients with dysplasia associated with carcinoma than in patients with dysplasia in benign Barrett's oesophagus ($P<0·01$). This may provide a reproducible means of quantifying progression and risk in serial follow-up.

Randomized controlled study of the gastrin receptor antagonist proglumide in the treatment of gastric cancer

J.D. Harrison, J.A. Jones and D.L. Morris, *Department of Surgery, University Hospital, Queen's Medical Centre, Nottingham, UK*

In spite of advances in surgery and anaesthesia there has been no improvement in the prognosis of gastric carcinoma over the last 70 years, and there is no safe and effective form of treatment for advanced disease. Gastrin is known to be a trophic agent to gastric mucosa, and proglumide has been shown to inhibit the growth of gastric carcinoma cell lines and xenografts[1].

To investigate the effect of proglumide in patients with advanced gastric cancer, 85 patients were randomized after stratification for severity of disease to a treatment group which received proglumide 800 mg q.d.s., or to join an untreated control group. Patients were followed up at regular intervals using time of death from randomization as the end point. The control and treatment groups were age-matched, but there was an excess of men in each group. The mean follow-up to date is 40 weeks and 44/85 (52 per cent) of the patients have died. The median survival in the control group was 170 days (95 per cent confidence interval 65–275 days), whilst in the treated group the medial survival was 204 days (95 per cent confidence interval 118–289 days), the generalized Wilcoxon statistic = 2·04, $P=0·15$.

These data suggest that there may be a survival advantage to be gained from using gastrin receptor antagonists in the therapy of gastric cancer.

Hepatic perfusion index: pause for thought

D. Hemingway, S. Grime, D.M. Nott, D Chang, S.A Jenkins and T. Cooke, *Departments of Surgery and Nuclear Medicine, Royal Liverpool Hospital, Liverpool, UK*

The hepatic perfusion index (HPI) derived by dynamic hepatic scintigraphy (DHS) predicts the presence of micrometastases in man. We have shown similar alterations in the HPI of rats with hypervascular hepatic tumours and have demonstrated that these changes resulted from a decrease in portal venous inflow (PVI) and arteriovenous shunting. We have now repeated these studies on hypovascular tumours which are more representative of those found in man.

Hepatic and systemic haemodynamics, arteriovenous shunting and HPI were determined in rats 2, 6, 10 and 20 days after intraportal administration of 10° HSN sarcoma cells. Overt hepatic tumour was present at 20 days. However the mean(s.d.) HPI in animals with tumour (47·2(4·1)) was significantly greater ($P<0·002$, Student's t test) than in controls (35·2(2·97)) at 10 days and remained elevated at 20 days. Hepatic artery flow was unchanged throughout the study but PVI was significantly decreased ($P<0·001$) at 10 and 20 days. No arteriovenous shunting occurred during the growth of the tumour.

These results indicate that in slow growing hypovascular hepatic tumours, changes in the HPI occur late in their development and are related to a reduction in PVI, suggesting that DHS may not predict very early tumours in man.

Immunohistochemical study of a new monoclonal antibody, MC3, in pancreatic tissues

N. Rothnie, H. Su, N. Rooney*, E Dankwa*, P. Newcomb, C. Wood† and N. Habib, *Departments of Surgery and *Histopathology, Bristol Royal Infirmary, and †Royal Postgraduate Medical School, London, UK*

Adenocarcinoma of the pancreas has a low 5-year survival rate. Diagnosis is often late when there is minimal chance of cure. Radiolabelled monoclonal antibodies may offer a new approach in management. The aim of this study was to assess the immunohistochemical pattern of staining in normal and diseased pancreas using a new murine monoclonal antibody, MC3, raised against a human colorectal carcinoma.

Formalin-fixed, paraffin-embedded tissue sections from patients with adenocarcinoma of the pancreas ($n=14$), acute pancreatitis ($n=10$), chronic pancreatitis ($n=4$), gastrinomas ($n=4$), insulinomas ($n=2$) and normal pancreas ($n=11$) were stained with MC3 using the avidin–biotin peroxidase method. Staining was assessed according to the cytological distribution and the percentage of cells staining (none, 10 per cent, 10–50 per cent, >50 per cent) The results are shown in the *Table*.

		Staining with MC3			
	n	None	<10%	10–50%	>50%
Normal pancreas	11	8	3		
Chronic pancreatitis	4	4			
Acute pancreatitis	10	10			
Adenocarcinoma	14			3	11
Gastrinoma	4	3	1		
Insulinoma	2	1	1		

Staining was localized to the apical membrane, superficial mucin and supranuclear cytoplasm of tumour cells Over 50 per cent of cells staining was taken as a positive level (χ^2 normal *versus* carcinoma, $P<0{\cdot}001$, pancreatitis *versus* normal $P<0{\cdot}001$) We conclude that MC3 recognizes a tumour associated antigen which on immunohistochemical staining is highly expressed on adenocarcinomas of the pancreas when compared with normal and benign pancreatic tissue.

Serum gastrin concentrations are elevated in colorectal cancer

R.M. Charnley, W.M. Thomas, J. Stanley and D.L. Morris, *Department of Surgery, University Hospital, Nottingham, UK*

Gastrin is an established trophic factor for benign and malignant colonic epithelial cells We have measured fasting serum gastrin levels by radioimmunoassay in 62 patients with colorectal cancer and in 18 age-matched patients who had a normal colonoscopy and no evidence of malignancy. In colorectal cancer patients the median serum gastrin level was 49·35 pg/ml (range 7·5–1300·0) and in patients with a normal colonoscopy 36·6 pg/ml (range 5·5–53·3), $P=0{\cdot}005$ (Mann–Whitney *U* test). Among the cancer patients, 26 per cent had elevated serum gastrin concentrations (greater than mean +2 s.d. of normals).

To determine the origin of the elevated serum gastrin, 54 colorectal cancer patients had tumour-draining mesenteric vein blood samples taken at surgery before their colonic resection and a peripheral venous sample was taken simultaneously Median gastrin concentration in mesenteric vein blood was 45·4 pg/ml (range 6·0–1100·0) and in peripheral blood was 49·3 pg/ml (range 7·5–1300·0), the values being very similar in individual patients (correlation coefficient $r=0{\cdot}99$)

In eight patients who underwent a curative resection, postoperative fasting gastrin levels were similar to preoperative levels ($r=0{\cdot}977$), confirming that the hypergastrinaemia in colorectal cancer patients is not due to tumour production but may be a causative factor in relation to tumour aetiology.

Increasing tumour capillary permeability enhances tumour uptake of antibody–isotope conjugate

T.W. Hennigan, R. Carpenter, R.H. Begent* and T.G. Allen-Mersh, *Departments of Surgery and *Medical Oncology, Charing Cross and Westminster Medical School, St Dunstan's Road, London, UK*

Treatment of colorectal liver metastases with antibody–isotope conjugates (AIC) is limited by the poor ratio of tumour to normal tissue uptake. We have improved tumour uptake of AIC by regional perfusion of two agents which increase capillary permeability – histamine and leukotriene C_4 (LTC_4)

Human colorectal carcinoma xenografts (LS174T) were grown in hind limbs of athymic rats to derive their circulation from the femoral artery Anti-carcinoembryonic antigen monoclonal antibody (A5B7) conjugated with ^{131}I was infused either regionally via the femoral artery ($n=12$) or systemically via a lumbar vein ($n=12$) In a further 19 animals the AIC was mixed with histamine ($n=12$, 10 mg/kg) or LTC_4 ($n=7$, 25 μg/animal) and delivered via the regional cannula. The cannula was removed after 1 h and the animal recovered After 48 h the animal was killed. Tumour and liver were weighed and γ activity measured in a well counter. The results are shown in the *Table*.

	Tumour:liver ratio (counts/g)	Significance of difference compared with systemic delivery
Systemic delivery	1·22(0·40)	–
Regional delivery	1·62(0·56)	n.s.
Histamine	3·26(0·89)	$P<0{\cdot}01$
LTC_4	2·88(0·71)	$P<0{\cdot}05$

Values mean (s.d.)

Regional delivery slightly increased tumour AIC uptake 33 per cent However, addition of histamine or LTC_4 produced a three-fold increase in AIC uptake compared with systemic delivery.

Chromosome 5 deletion map around the gene for familial adenomatous polyposis in non-familial colorectal cancer

M.G. Dunlop, P. Ashton-Rickardt and A.H. Wyllie (introduced by A.N. Smith), *MRC Human Genetics Unit, Western General Hospital, Edinburgh and Department of Pathology, Edinburgh University, Edinburgh, UK*

The familial adenomatous polyposis (FAP) gene maps to chromosome 5q21. Somatic mutation of both copies of this putative tumour suppressor gene is hypothesized to occur in sporadic colorectal carcinomas but supporting evidence is insubstantial. We report a detailed deletion map of chromosome 5 in 118 sporadic colorectal carcinomas Using 12 previously mapped polymorphic DNA probes, matched tumour and blood leukocyte DNA preparations were analysed for loss of constitutional heterozygosity close to the FAP gene and at loci spanning chromosome 5. Allele loss at any heterozygous locus was noted in 51 of 114 tumours (45 per cent), rising to 54 per cent (35/65) where 5q21 probes flanking the FAP gene were both heterozygous. These losses comprised 18 interstitial deletions, five long arm losses, four mitotic recombinations and one whole chromosome loss The remainder could not be assigned due to limited heterozygosity. Patterns of allele loss were consistent with specific involvement of a gene located between probes C11P11 and YN548, which closely flank the FAP gene Allele loss did not correlate with Dukes' classification, suggesting early, perhaps causative, involvement.

This study demonstrates the nature and frequency of chromosome 5 allele loss in sporadic colorectal cancer The data suggest specific involvement of the FAP gene itself.

Site-dependent sensitivity of Haemoccult® screening: implications for test design

W.M. Thomas, G. Pye and J.D. Hardcastle, *Department of Surgery, University Hospital, Nottingham, UK*

Haemoccult® (Norwich Eaton Ltd., Newcastle upon Tyne, UK) utilizes the pseudoperoxidase activity of haematin to detect faecal occult blood Non-haemolysed blood (fresh rectal bleeding) or excessively degraded haemoglobin (proximal colonic bleeding) is thought to produce false negative reactions.

We report the site distribution of cancers missed by Haemoccult in a screening study for colorectal neoplasia. Haemoccult tests were completed on 32 213 subjects (age range 50–74 years); 2·1 per cent were positive Further investigation revealed 94 carcinomas (rectum, 16; sigmoid/descending colon, 63; transverse colon, six; ascending colon and caecum, nine) Twenty-four carcinomas have presented in the 2-year period following a negative test; these are presumed to have been missed by Haemoccult (rectum seven, sigmoid/descending colon eight, transverse colon two, ascending colon and caecum seven)

These data suggest that Haemoccult misses 30 per cent of rectal cancers, 12·5 per cent of sigmoid/descending colon cancers, 25 per cent of transverse colon cancers and 44 per cent of those in the ascending colon or caecum. A greater proportion of missed cancers were rectal ($\chi^2=4{\cdot}00$, $P<0{\cdot}05$) or in the caecum/ascending colon ($\chi^2=8{\cdot}59$, $P<0{\cdot}01$) than in the sigmoid/descending colon.

Haemoccult varies in sensitivity from 56·2 per cent for right-sided cancers to 87·5 per cent for sigmoid/descending colon cancers. Tests not dependent on haematin may demonstrate increased sensitivity for rectal and right-sided neoplasia

Increased compliance rates anticipated with the use of self-administered tests for faecal occult blood (FOB) screening are not observed in a randomized controlled trial

J. Verne, J.D. Kettner, C. Whatrup, D. Mant*, A. Farmer†, K. Miller, N.J.McC. Mortensen‡ and J.M.A. Northover, *ICRF Colorectal Unit, St Mark's Hospital, London, †Department of Community Medicine and General Practice Oxford, Thame Health Centre and ‡John Radcliffe Infirmary, Oxford, UK*

Compliance is a major determinant of the efficacy of screening for colorectal cancer. Performance of conventional tests requiring manipulation of faeces is thought to be a major factor causing non-compliance[1]. New guaiac based self-administered tests (SATs) like Early Detector (ED) and Coloscreen Self-Test (CST) require little or no direct manipulation of faeces.

To test the hypothesis that compliance could be improved by using SATs a randomized controlled trial was conducted in the general practice setting comparing compliance using two SATs, ED and CST with Haemoccult® (Norwich Eaton Ltd., Newcastle upon Tyne, UK) (H). The effect of dietary restriction on compliance and positive rates for the three tests was also evaluated. A total of 1847 individuals were randomized by household into six groups (each receiving one test, with or without dietary restrictions). Overall compliance was 53 per cent. Logistic regression was used for the analysis to account for interaction between predictors of compliance. Neither test method nor dietary restriction had significant effects on compliance. The positivity rate was significantly greater for ED (mean = 15·2 per cent) than H (mean = 4·1 per cent) or CST (mean = 2·0 per cent). Furthermore, for H positivity was not reduced by dietary restriction.

The results show that the use of SATs failed to produce the anticipated increase in compliance rates. Faecal manipulation and dietary restriction are unlikely to be significant obstacles to compliance.

Colorectal cancer screening: does a false negative result adversely affect tumour stage?

W.M. Thomas, G. Pye and J.D. Hardcastle, *Department of Surgery, University Hospital, Nottingham, UK*

Haemoccult® (Norwich Eaton Ltd., Newcastle upon Tyne, UK), a faecal occult blood test, has a false negative rate for cancer of 25–35 per cent in screening studies. It is of concern that the reassurance offered by such a result will delay presentation once the cancer becomes symptomatic.

We have compared tumour stage in those cancers thought to have been missed in a Haemoccult screening study for colorectal neoplasia with those diagnosed in a control group not offered the test. Twenty-four carcinomas have presented symptomatically in 31 536 subjects (age 50–74 years) following negative Haemoccult tests in the 2-year interval before being offered a retest (interval cancers). Seven (29 per cent) were Dukes' A, five (21 per cent) were Dukes' B, six (25 per cent) Dukes' C and six (25 per cent) Dukes' D.

In the control group (61 996 persons) 164 cancers have been diagnosed (16 (10 per cent) Dukes' A, 53 (32 per cent) Dukes' B, 55 (33·5 per cent) Dukes' C and 40 (24 per cent) Dukes' D).

Significantly more interval cancers were at Dukes' A than control group cancers ($\chi^2 = 7{\cdot}35$, $P < 0{\cdot}01$); there was no statistical difference for other tumour stages.

Whilst accepting a possible selection bias in favour of the interval group, these findings suggest that a false negative Haemoccult result does not adversely affect tumour stage in a colorectal cancer screening programme.

Crypt cell production rate (CCPR) of the colon following chemical carcinogenesis administration

C. Hall, S.H. Silverman and M.R.B. Keighley, *Birmingham General Hospital, Steelhouse Lane, Birmingham, UK*

It has been proposed that there is a cause and effect relationship between the CCPR, tumour formation and established colorectal cancer in experimental animals (and by extrapolation in humans) but the evidence is incomplete.

In order to study this further, the CCPR was determined in a cohort of 75 female Wistar rats undergoing carcinogenesis using 1,2-dimethylhydrazine (DMH) 40 mg/kg weekly for 5 weeks, control animals were injected with the DMH carrier. The CCPR was determined after giving 1 mg/kg vincristine intraperitoneally followed by serial sacrifice of three animals per time point at 1, 1·5, 2, 2·5 and 3 h. All stathmokinetic analyses were performed by an independent blind observer.

At 10 weeks no animals had colorectal tumours compared with 80 per cent at 25 weeks. Before DMH the mean (s.e.m.) CCPR was 3·31 (0·55) cells/crypt/h. At 10 weeks this was 3·63 (0·89) in controls and 7·64 (1·09) in DMH animals ($P < 0{\cdot}001$, Student's *t* test) and 2·99 (0·43) *versus* 1·05 (0·68) respectively at 25 weeks.

Although the colonic CCPR was increased after DMH, it was not sustained into tumour formation. This may suggest that changes in CCPR previously observed are linked to drug administration rather than tumour formation itself.

Immunoscintigraphy in the detection of recurrent colorectal cancer: evaluation in conjunction with computed tomographic scanning

R.M. Charnley, A.C. Perkins*, K.C. Ballantyne, M.L. Wastie*, S.S. Amar† and J.D. Hardcastle, *Departments of Surgery, *Medical Physics and †Radiology, University Hospital, Nottingham, UK*

Immunoscintigraphy using an indium-labelled anti-carcinoembryonic antigen monoclonal antibody, C46 (Amersham International), has been compared with computed tomographic (CT) scanning in the detection of abdominal and pelvic recurrence from colorectal cancer. The detection of liver metastases was not evaluated.

Thirty patients with suspected recurrent carcinoma have been imaged using both techniques. All images were read blindly, no clinical information being available to the observers. Eighteen patients had 22 individual recurrences (12 pelvic and 10 abdominal), 15 confirmed by histology, two by operation and five by disease progression. Twelve patients, negative for recurrence, were followed up for a median time of 16 months (range 6–19 months). The results are shown in the *Table*

	Detection of recurrence	
	Sensitivity (lesions detected) (%)	Specificity (%)
Immunoscintigraphy	82	36
CT scan	68	95

Because of the absence of fat around the bowel in the abdomen, CT scanning was less accurate in the abdomen than in the pelvis. In five patients recurrence was missed by CT scan and in four of these it was detected by immunoscintigraphy, three of these four patients having abdominal disease. Immunoscintigraphy detected 90 per cent of abdominal recurrences against 60 per cent detected by CT scan.

Immunoscintigraphy is particularly sensitive in the identification of recurrent colorectal cancer within the abdomen where CT scanning is less accurate.

Endoscopic transanal resection of rectal tumours: preliminary report

A.R. Berry, N.J.McC. Mortensen and M.G.W. Kettlewell, *Department of Surgery, John Radcliffe Hospital, Oxford, UK*

Abdominoperineal resection and anterior resection are major operations for elderly frail patients or for those requiring palliation. Endoscopic transanal resection (ETAR) of rectal tumours, using a large diameter resectoscope, is by contrast a relatively simple and inexpensive procedure. We have performed 137 ETARs in 81 patients with a 30-day mortality of 11·1 per cent and postoperative complications occurred after 21 of the 137 procedures (15·3 per cent).

Thirty-one (38 per cent) were resected for palliation. In this group ETAR abolished or improved rectal bleeding in 66 per cent of patients, diarrhoea in 77 per cent of patients, faecal incontinence in 50 per cent of patients and rectal pain (including tenesmus) in 50 per cent of patients.

Twenty-three patients (28 per cent) were treated for large benign rectal polyps. Symptoms were universally abolished and the technique is particularly suited to the management of these patients.

Twenty-eight patients with theoretically 'curable' rectal cancer were resected with a 78 per cent survival at 1 year. Long-term survival and recurrence rates in this group remain to be assessed, but 21 have died with a median survival of 13 months.

ETAR is a useful repeatable technique for treating selected patients with rectal tumours. In elderly patients it has an acceptable mortality and morbidity.

Safe parameters for contact Nd:YAG laser palliation of colorectal cancer

A. Wyman, H.M. Sweetland and K. Rogers, *University Surgical Unit, Northern General Hospital, Sheffield, UK*

Non-contact Nd:YAG laser vaporization of advanced colorectal cancer is associated with perforation rates of up to 7 per cent. Contact Nd:YAG laser probes may produce more precise thermal effects. The tissue effects of contact laser probes have been investigated.

Contact Nd:YAG laser insults were inflicted on human colorectal carcinomas and adjacent normal bowel wall *in vitro*. Laser powers of 5–30 W in pulses of 1–5 s produced total energies of 5–125 J.

Depth of tissue vaporization and coagulation in normal bowel wall and tumour were not significantly different at all energies ($P > 0{\cdot}1$, Mann–Whitney *U* test). In normal bowel, vaporization was confined to mucosa and submucosa at total energies <30 J. At energies of 30–50 J, 18/39 lesions (46 per cent) penetrated the muscularis and 3 of 39 (8 per cent) produced perforation. At energies >50 J 26 of 57 lesions (46 per cent) penetrated the muscularis and a further 26 of 57 (46 per cent) produced perforation. Ulcerated pale tumour was more resistant to vaporization than other tumour tissue, mean (s.d.) vaporization depths being 1·32 (0·2) mm and 2·74 (0·58) mm respectively at 75 J total energy ($P < 0{\cdot}02$).

Contact laser probes produce predictable depths of tissue vaporization and coagulation. Ulcerated pale colorectal tumour is relatively resistant to vaporization. There is a significant risk of bowel perforation at total energies exceeding 50 J.

Transcription of *c-myc* mRNA and protein product is a potential prognostic indication in colorectal cancer

S. Rowley, J.P. Neoptolemos, I.A. Donovan and M.R.B. Keighley, *Dudley Road Hospital, Birmingham and Department of Surgery, University of Birmingham, UK*

Variation in oncogene expression may be one of the ways in which a tumour acquires ever more malignant characteristics.

Southern blotting using a DNA probe recognizing all three exons of the *c-myc* gene showed no evidence of DNA amplification in 12 fresh colorectal tumours of all four stages of Dukes' classification. However, quantitative dot blotting of mRNA transcript revealed a variation from unity to eight-fold when compared with a high *c-myc* expressing cell line, COLO 320.

Varying levels of the nuclear expressed protein product in *c-myc*, p62 *c-myc* in archival paraffin-embedded material were demonstrated by a flow cytometric assay[1]. A double labelling technique was used to quantify the protein of extracted nuclei with a monoclonal antibody (MYC1 6E10) and a second fluorescein labelled immunoglobulin and quantitated by flow cytometry. Protein levels correlated well using this technique to mRNA levels ($r = 0{\cdot}8$; $P < 0{\cdot}002$).

A preliminary study in 83 patients revealed low levels of p62 *c-myc* correlated to survival in patients followed up to 5 years (log rank analysis $\chi^2 = 4{\cdot}69$; $P = 0{\cdot}03$, d.f. = 1).

It is concluded that p62 *c-myc* expression can be quantitated by flow cytometry and correlates with mRNA levels and appears to be related to prognosis.

Intraoperative detection of cancer using radiolabelled antibodies: clinical use and experimental evaluation

B.R. Davidson, W.A. Waddington*, M.D. Short* and P.B. Boulos, *Department of Surgery, University College and Middlesex School of Medicine and *Department of Medical Physics, University College Hospital, London, UK*

Radiation detectors may allow small cancer deposits to be detected intraoperatively following radiolabelled antibody administration. A clinical evaluation was carried out on 16 patients with colorectal tumours (14 cancers, one adenoma, one lipoma) with the indium (^{111}In)-labelled monoclonal antibody ICR2, recognizing the tumour associated epithelial membrane antigen (EMA). At operation counting was carried out (3 × 20 s/site) over the primary cancers and any palpable mesenteric nodes (all <1 cm diameter). The tumour/normal colon ratio (T/NC) of counts *in vivo* was $>1{\cdot}5:1$ in nine of the 14 patients with cancer (mean(s.d.) 1·83 (0·21):1), 0·96:1 and 1·06:1 in the two patients with benign tumours and node/normal colon ratio higher in those containing metastases (mean (s.d.) 1·7 (0·06):1 *versus* 0·84 (0·33):1, $P = 0{\cdot}017$). EMA expressing cancers had higher T/NC ratios on well counting (mean(s.d.) 2·45 (0·65):1 *versus* 1·30 (0·25):1, $P = 0{\cdot}005$).

Following clinical evaluation an abdominal tumour model was used to assess the limitations of this technique. Spheres of 0·5–10 ml representing tumour deposits were suspended in a tank of ^{111}In representing background or normal tissue radioactivity. The ratio of radioactivity in the tumour to that of the background was varied from 2:1 to 8:1. The tumour was considered to be detectable if the mean counts over the tumour exceeded that of the background by two standard deviations. At 2:1 only tumours of 10 ml could be detected. At 8:1, 1 ml tumours were detected.

We conclude that small tumour deposits may be detected intraoperatively with indium-labelled monoclonal antibodies but that high uptake ratios (T/NC) are required.

Pretreatment with MPA enhances actions of cytotoxic drugs on MCF-7 cells: a possible mechanism of such action?

N.A. Shaikh and M.W. Ghilchik, *Breast Clinic, St. Mary's Hospital, London, UK*

Pretreatment with medroxyprogesterone acetate (MPA) enhances the response of breast cancer cells to cytotoxic agents[1]. Evidence to support this was presented to the SRS in July 1988. MPA increases the cytotoxicity of methotrexate (MTX) and vincristine[2] as well as Adriamycin® (ADR) (Farmitalia Carlo Erba, St. Albans, UK) and this action of MPA seems to be independent of its growth inhibitory effect. A possible mechanism may be the reduction of receptor levels.

To investigate this possibility, the receptor negative breast cancer cell line MDA-MB-231 was used. The cells were exposed to MPA or control medium for 48 h, followed by chemotherapy drug (ADR or MTX) or control medium for 24 h. The washed cells were then allowed to proliferate for 3–4 days before being harvested and counted. The effect of MPA at a concentration of 40 nM on these receptor negative cells was not significant ($P = 0{\cdot}1$) and pretreatment with MPA did not enhance the cytotoxic effect of MTX or ADR.

The findings of enhancement of cytotoxicity of MTX and ADR by MPA on receptor positive cells, while no such action was obtained on receptor negative cells, suggests that this action of MPA may be receptor mediated.

2. Shaikh NA, McNeil JM, Patel K, Ghilchik MW, Braunsberg H. Interactions between E_2, MPA and cytotoxic drugs in human breast cancer cells in culture. *J Steroid Biochem* 1987, **28**(Suppl): 1585.

Stimulation of endogenous production of tumour necrosis factor during intracompartmental therapy with interleukin 2 receptor

D.H. Johnston, P. Allen, M.G. Macey*, A.C. Newland*, M.F. Grahn, P. Durdy and N.S. Williams, *The Surgical Unit and *Department of Haematology, The London Hospital, Whitechapel, London, UK*

The antitumour efficacy of interleukin 2 (IL-2) is believed to be mediated by generation of lymphokine activated killer (LAK) activity amongst peripheral blood lymphocytes (PBL). This can be measured as enhanced activity to standard target cell lines in direct cytotoxicity assays *in vitro*. Enhanced lytic activity in PBLs is predominantly due to activation of natural killer cells (CD3−, CD16+, LGLs). However, during successful adaptive cellular immunotherapy few cells (1 per cent) of this phenotype infiltrate the tumour, suggesting that direct lysis (as measured in target cell assays) may not be the only mechanism of antitumour activity during LAK therapy.

We have serially analysed tumour necrosis factor α (TNF) in peritoneal cavity fluid during intraperitoneal generation of LAK cells from PBLs. LAK activity was confirmed *in vitro* by demonstration of significantly increased cytotoxic activity to K562 ($P<0{\cdot}01$) and Daudi ($P<0{\cdot}01$) targets. Paired target lysis assays showed good correlation ($r=0{\cdot}58$, $P<0{\cdot}01$, $n=52$) between the sensitivity of these two target cell lines.

Significant stimulation of endogenous TNF production was apparent in all of six treatment cycles studied in five patients (range 22–800 pg/ml). There was no apparent correlation between TNF levels and cytotoxic activity to either target cell ($n=48$).

The full spectrum of biological activity of IL-2r is not reflected by *in vitro* cytotoxicity assays. Antitumour activity may be mediated *in vivo* by a cascade release of cytokines, TNF production may contribute to this activity.

Treatment of liver metastases by cryotherapy

R.M. Charnley, J. Doran and D.L. Morris, *Department of Surgery, University Hospital, Nottingham, UK*

We have developed a new design of cryoprobe which enables freezing of an intrahepatic lesion with minimal destruction of surrounding tissue. The cryoprobe has a 5 mm diameter shaft and a copper tip through which liquid nitrogen circulates at −196°C. The probe is inserted into the lesion at laparotomy under intraoperative ultrasound control and coolant is circulated producing a sphere of liver destruction, the size of which can be monitored by intraoperative ultrasound.

Eight patients with liver metastases (six colorectal, one carcinoid and one ovarian) have undergone cryotherapy of a total of 42 metastases (range 3–12 metastases/patient), eight of which were impalpable and detectable only by intraoperative ultrasound. All patients were discharged 5–10 days postoperatively and there were no complications. The patient with carcinoid has been relieved of his symptoms of flushing and diarrhoea and in three of four colorectal patients followed up for 3 months serum carcinoembryonic antigen has decreased, in one patient to undetectable levels. Computed tomographic scans have shown defects in the liver substance corresponding to the frozen metastases.

Cryosurgery of the liver using this novel system may provide an alternative techique for the treatment of patients with small numbers of unresectable liver metastases.

Is the use of the cell separator an alternative to transfusion with banked blood during cancer surgery?

J.N. Primrose and Carol Ramsden, *University Department of Surgery, St James's University Hospital, Leeds, UK*

Perioperative transfusion using banked blood worsens the prognosis in patients undergoing cancer surgery[1]. Autologous transfusion utilizing a cell saver avoids this problem but risks the dissemination of tumour cells in the red cell concentrate (RCC). The aim of this study was to determine whether viable tumour cells remained in the RCC after separation using a cell saver.

Units of whole blood were inoculated in duplicate with 4×10^7 cells from four tumour cell lines (breast cancer SKBr3, colon cancer COLO 320; erythroleukaemia K562 and lymphoma DAUDI) and processed using a Haemonetics® cell saver which produces a RCC and a waste saline wash. The saline washes were examined microscopically for tumour cells, 50 ml was spun at 500 *g* for10 min and the pellet cultured in appropriate media at 37°C in 5 per cent CO_2. The RCCs were sedimented on a Ficoll gradient, the 'mononuclear' layer removed, washed, examined for tumour cells and cultured as above.

No tumour cells were seen in the saline washes but all cell lines were easily seen after Ficoll separation of the RCC. All except DAUDI grew within 24 h and continued to grow after passage at 1 week. Occasional cells from the K562 and SKBr3 lines grew from the saline wash, but only after 72 h.

Thus viable tumour cells remain within the RCC after separation. The cell separator cannot be recommended for cancer surgery in which the tumour may be breached.

p53 gene mRNA expression in breast cancer

A.M. Thompson, C.M. Steel* and U. Chetty, *Department of Surgery, Royal Infirmary, Edinburgh and *MRC Human Genetics Unit, Western General Hospital, Edinburgh, UK*

The gene for p53, a 53 kDa phosphoprotein, maps to the short arm of chromosome 17, an important region in breast cancer. p53 has been implicated in cell immortalization and cotransformation and as an anti-oncogene.

Since p53 protein is short-lived, p53 messenger ribonucleic acid (mRNA) merits study. We therefore examined p53 mRNA expression in 49 untreated and 14 tamoxifen-treated consecutive breast cancers (where sufficient tissue was available) and in breast cancer cell lines. Total RNA fixed to nylon membranes was probed using a radiolabelled cDNA probe for p53. The resulting northern blot autoradiographs allowed qualitative and quantitative measures of p53 mRNA.

The cell lines MCF7, T47D and MDAMB231 all exhibited four species of p53 message; breast tumour tissues yielded only one of these four, a 2·8 kb mRNA. This message was detected in 28 of 49 (57 per cent) untreated and seven of 14 (50 per cent) tamoxifen-treated tumours; 15 untreated and three tamoxifen-treated tumours had high levels of mRNA similar to the breast cell lines. However, there was no significant correlation between p53 mRNA expression and tumour size, node metastasis or oestrogen receptor protein.

p53 messenger RNA therefore does not relate to known prognostic parameters in breast cancer.

Relation to mitotic activity of parathyroid adenomas to thallium-201 uptake

G.L. Carlson, B.K. Shenton, B. Clayton, J.R. Farndon and I.D.A. Johnston, *Departments of Surgery, Universities of Newcastle upon Tyne and Bristol and Department of Medical Physics, Royal Victoria Infirmary, Newcastle upon Tyne, UK*

Thallium isotope scintigraphy remains an unpredictable and controversial investigation for the preoperative localization of parathyroid adenomas. The mechanisms of cellular thallium accumulation are not understood. *In vitro* studies[1] suggest that increased uptake of thallium may follow malignant transformation and increased growth rate. A comparison was made between thallium uptake and mitotic activity in 24 parathyroid adenomas. Thallium localization was performed by a standard technique of scintiscanning, while mitotic activity was assessed by DNA analysis with flow cytometry. Adenomas were designated 'correctly' or 'incorrectly' localized by comparing the findings of preoperative scanning with those at surgery including histological examination and mitotic activity designated 'normal' or 'excessive' by reference to the 95 per cent confidence interval for the mean percentage of resting cells in a previous sample of 12 histologically normal parathyroid biopsies.

Fifteen of the 24 adenomas showed excessive mitotic activity and 13 of these (87 per cent) were localized correctly, while of the remaining nine adenomas only five (56 per cent) were localized correctly (χ^2; $P<0{\cdot}01$). There was no significant difference in gland weight between the two groups. These findings provide *in vivo* support for the hypothesis that thallium uptake is related to mitotic activity, and may also explain the limitations of this technique in localizing parathyroid adenomas.

Age matching improves the results of renal transplantation with older donors

P.K. Donnelly, A.R. Simpson, M.L. Nicholson, T. Horsburgh, P.S. Veitch and P.R.F. Bell, *Department of Surgery, Leicester General Hospital, Leicester, UK*

To cope with rapidly rising transplant waiting lists, kidneys taken from older cadaver donors are increasingly being used, but are unfortunately associated with inferior results, despite good HLA matching[1]. At this centre 40 per cent of locally harvested kidneys come from donors over 50 years of age. One solution not previously tested is the possible benefits of matching donor and recipient age.

In this study we examined the simultaneous effect of donor and recipient age on the graft survival of 141 consecutive first cadaver transplant recipients treated by cyclosporin immunosuppression. Individually there was no significant effect of recipient age whilst donors >50 years were associated with significantly worse ($P<0{\cdot}01$) graft survival than younger donors. Multivariate analysis, taking into account other variables of moderately matched recipients (i.e. dialysis time and type, donor/recipient sex, local/imported kidneys, rejection episodes, max./recent sensitivity, operation time, total ischaemic time, pre- and perioperative transfusion) indicated that donor–recipient age *difference* was the most important variable ($P<0{\cdot}05$) in determining graft success. For donors aged >50 years the 1-year graft was significantly improved when transplanting recipients no more than 5 years older than the donor Donor age should be an important recipient selection criterion in cadaveric renal transplantation

1. Foster MC *et al* Use of older patients as cadaveric kidney donors. *Br J Surg* 1988, **75**: 767–9.

Clinical application of transrectal and abdominal ultrasound with cytology in the detection of recurrent bladder tumours

A.H. Davies, T. Meagher, D. Cranston, W.H. Turner and G.J. Fellows, *Department of Urology, Churchill Hospital, Oxford, UK*

Check cystoscopies form a major part of the urological workload Davies *et al.*[1] have shown that the combination of transrectal and abdominal ultrasound will detect 95 per cent of tumour recurrence in the anaesthetized patient. In these patients combination ultrasound and cytology had a sensitivity of 100 per cent. This study was performed to see if similar results could be obtained when the patients were responsible for their own bladder filling and not anaesthetized.

Seventy-six patients (62 men, 14 women) of mean age 66 years (range 41–78 years) with previously known tumours were examined using the Bruel and Kjaer 1846 ultrasound machine using the 4 MHz abdominal probe and the 7 MHz transrectal probe, and urine was sent for cytology The following week cystoscopic examination was performed under general anaesthetic Thirty-seven patients (49 per cent) had recurrent tumour at cystoscopy; 78 per cent were detected by abdominal ultrasound, 73 per cent by transrectal ultrasound and 89 per cent in combination Cytology detected 59 per cent of recurrences and the sensitivity of combination ultrasound with cytology was 95 per cent. The false positive rate was 3 per cent. In certain patients bladder filling was inadequate, and obesity and rectal pathology made abdominal and transrectal ultrasound impossible. All patients stated a preference for ultrasound follow-up.

These results, obtained in an outpatient environment, are similar to those obtained in the anaesthetized patient[1] and will allow us to modify our mode of follow-up of bladder tumours accordingly.

Use of damage to the proximal tubules to predict the development of acute tubular necrosis

F T. Lam, S.R. Aparacio and G.R. Giles, *Departments of Surgery and Pathology, St. James's University Hospital, Leeds, UK*

It is assumed that delayed graft function results from acute tubular damage. We preserved five canine kidneys with hyperosmolar citrate (HOC) and five with phosphate buffered sucrose (PBS) solutions for 72 h before autotransplantation. Post-preservation biopsies were examined qualitatively and quantitatively using the method described by Burke *et al*[1] in which brush border integrity and numbers of damaged proximal tubular cells are calculated. Using a computerized digitizing tablet tubular and cellular parameters were measured (see *Table*). This indicates that PBS-preserved kidneys show more evidence of tubular injury than those preserved with HOC. Despite biopsy changes the serum creatinine levels of PBS-preserved kidneys are significantly lower than those preserved with HOC

	PBS		HOC		*P* value
Percentage proximal tubules with intact brush border	15·4	(4·4)	18·4	(3·6)	n s
Percentage injured proximal tubule cells	57·2	(12·2)	39·3	(6·5)	n.s.
Luminal area/tubule wall area	0·27	(0·03)	0·46	(0·04)	<0·05
Luminal area/cell area	50·9	(5·5)	76·2	(7·9)	<0·05
Mean maximum creatinine (μmol/l)	285	(20)	990	(206)	<0·05

Values are mean(s.d.)

It is concluded that the likelihood of immediate function is related to factors other than proximal tubular injury during storage.

Relevance of ambulatory monitoring in patients with neurogenic bladder dysfunction and upper tract dilatation

R.J. Webb, D.E Neal and I.D.A. Johnston*, *Department of Urology and *University Department of Surgery, Newcastle upon Tyne, UK*

In neurogenic bladder dysfunction high end filling pressures and poor compliance during fast bladder filling are associated with upper tract dilatation Previous studies have shown important differences between conventional cystometry with artificial filling (CMG) and ambulatory monitoring during natural bladder filling (AM). This prospective study compares the ability of CMG and AM in predicting upper tract dilatation in patients with neurogenic bladders.

Forty-three patients (31 men, 12 women, mean age(s.d.) 30 (26) years) with neurogenic bladder dysfunction and low compliance on CMG were studied by both CMG and AM. The pressure rise during filling on CMG (5±cmH$_2$O; $P<0{\cdot}0001$, Mann–Whitney U test), despite similar filling volumes. Phasic bladder activity was observed more often during AM ($n=35/43$) than during CMG ($n=19/43$; McNemar's $\chi^2+12{\cdot}5$; $P<0{\cdot}001$). In patients with upper tract dilatation both the mean(s.d.) frequency and amplitude of this phasic activity were greater during AM (42(10) contractions/h and 231(98) cmH$_2$O/min) compared with those with normal upper tracts (8·3 (6·7) contractions/h and 156(70) cmH$_2$O/min; both $P<0{\cdot}001$; Mann–Whitney U test) but end filling pressures were not different on CMG.

High end filling pressures were not found on natural filling in neuropathic bladder dysfunction but high frequency phasic activity was found and was closely associated with upper tract dilatation.

β_2-microglobulin: a sensitive index of renal impairment in obstructive jaundice

P.J. Donaldson, A.W. Goode and C.V. Mann, *Surgical Unit, the London Hospital, London, UK*

Renal impairment is a major factor in the morbidity associated with surgery for obstructive jaundice. To investigate the nature of renal impairment in obstructive jaundice, β_2-microglobulin (β_2M) in serum and urine has been measured by radioimmunoassay in 23 jaundiced patients and 16 controls.

The median preoperative serum β_2M level in jaundiced patients (2·22 mg/l, range 1·054–3·975) was significantly higher than on entry (1·6445 mg/l, range 1·025–1·774, $P<0{\cdot}005$ Mann–Whitney U test). Urinary β_2M concentration and the urine serum ratio did not differ significantly between the two groups. There was a strong correlation between serum bilirubin and serum β_2M ($r_s=0{\cdot}65$, $P<0{\cdot}001$, Spearman rank correlation). The median urine:serum β_2M ratio in jaundiced patients (439, range 7–2988) was significantly higher than in the control patients (18, range 10–3610) on the first postoperative day, and on the third postoperative day (185, range 7–6167 and 13, range 2–4670 respectively, $P<0{\cdot}005$ Mann–Whitney U test).

These results suggest that damage to the proximal renal tubule is a contributory factor in the development of postoperative renal impairment in jaundiced patients. It is suggested that measurement of serum and urinary β_2M is of value in the assessment of renal function in jaundiced patients

Effects of different total parenteral nutrition (TPN) regimens on host antitumour immune responses

P.C. Sedman, T.G. Brennan, S.S. Somers, C.W. Ramsden and P.J. Guillou, *University Department of Surgery, St. James's University Hospital, Leeds, UK*

Total parenteral nutrition (TPN) with lipid-based regimens may be detrimental to endogenous antitumour immune mechanisms, the lipid component possibly being responsible for this immunodepression[1] Alternative lipid emulsions may be less suppressive. This study was designed to test this hypothesis

Thirty-six patients with gastrointestinal cancer consented to undergo 7 days of TPN prior to surgery. Each patient was prospectively randomized to receive one of three equicaloric regimens consisting of amino acids, the calories being provided either as glucose alone (G), glucose plus 20 per cent Intralipid (IL) or glucose plus 20 per cent medium-chain triglycerides (MCT). Measurements of natural killer (NK) and lymphokine-activated killer (LAK) cell activities were measured before the start and on day 7 of the study. Mean percentage cytotoxicity against the NK target (K562) and LAK cell targets (DAUDI and COLO) were as shown in the *Table*

	NK *versus* K562			LAK *versus* Daudi			LAK *versus* COLO		
	G	IL	MCT	G	IL*	MCT	G	IL*	MCT
Day 0	52(7)	47(5)	41(6)	43(12)	37(7)	34(11)	46(12)	64(7)	55(3)
Day 7	42(7)	41(6)	28(6)	32(10)	24(4)	44(17)	53(7)	39(5)	59(7)

Values are mean (s.e.m.). * $P<0{\cdot}05$

NK activity was unaffected by TPN in all groups. However, LAK cell generation was suppressed after 7 days of TPN with IL ($P<0{\cdot}05$) but by neither of the other regimens.

Since lipid is an important component of TPN, we suggest that MCT should be the regimen of choice for immunocompromised patients.

1. Monson JRT, Sedman PC, Ramsden CW, Brennan TG, Guillou PJ. Total parenteral nutrition adversely influenced tumour-directed cellular cytotoxic responses in patients with gastrointestinal cancer. *Eur J Surg Oncol* 1988; **14**: 435–43.

Glutamine-enhanced enteral diets in stressed dogs improves nitrogen balance without increasing portal ammonia

M. Brown, G.R. Campbell and B.J. Rowlands, *Department of Surgery, Queen's University of Belfast, and Institute of Clinical Science, Grosvenor Road, Belfast, UK*

During stress the jejunum is important in metabolizing glutamine to maintain mucosal integrity and release metabolites into the portal blood supporting hepatic protein production and gluconeogenesis. Few commercial feeds contain glutamine, therefore endogenous sources are broken down to maintain the jejunal requirement, leading to an increased negative nitrogen balance. Ammonia production by jejunal enterocytes during glutamine metabolism has prevented glutamine inclusion in standard feeds. To assess the effect of glutamine-enhanced enteral diets in the stress response on nitrogen balance and portal ammonia production the following experiment was carried out.

Groups of standard beagle dogs were stressed by a laparotomy with either an enterotomy (E) or 60 per cent enterectomy (T). These two groups received either a glutamine-free diet (C) or 30 per cent glutamine-enhanced diet (D). The diets were isocaloric and isonitrogenous. Daily nitrogen balance was calculated over 72 h and portal blood sampled for ammonia levels. The results are shown in the *Table*.

	Cumulative nitrogen balance (g/day)		
Group	Day 1	Day 2	Day 3
EC ($n=7$)	0·53 (0·82)	−0·37 (1·48)	−3·70 (3·38)
ED ($n=6$)	2·16 (1·27)	3·09 (1·76)	4·61 (0·99)*
TC ($n=5$)	1·25 (1·25)	0·68 (2·34)	−1·60 (6·63)
TD ($n=6$)	2·36 (1·05)	−0·09 (4·69)	−5·07 (2·79)

		Portal ammonia (mmol/l)					
	Fasting	1 h	6 h	18 h	24 h	48 h	72 h
EC	212(43)	252(50)	232(105)	237(13)	294(161)	169(120)	144(111)
ED	142(44)	181(66)	205(44)	166(96)	160(86)	124(69)	142(35)
TC	203(47)	216(61)	191(48)	190(68)	188(54)	154(45)	155(87)
TD	157(68)	225(59)	254(77)	267(111)	227(54)	181(137)	227(101)

Values are mean(s.d.) * $P<0{\cdot}005$, ANOVA

Glutamine-enhanced enteral diets improved nitrogen balance in stressed dogs without increasing ammonia release. Stressed patients may benefit from supplementary glutamine.

Improved respiratory muscle function after a short course of intravenous nutrition

P.M. Christie and G.L. Hill, *University Department of Surgery, Auckland Hospital, Auckland, New Zealand*

Protein depletion is a risk factor for postoperative pneumonia[1]. We assessed the effect of 14 days of preoperative intravenous nutrition (IVN) on respiratory muscle function. Nineteen patients (10 men, mean(s.d.) age 30 (12) years) who had lost 35 per cent of their protein stores associated with a 25–40 per cent level of respiratory functional impairment had repeated measurements of total body protein (TBP) by neutron activation analysis with measurements of respiratory muscle strength (RMS) and forced expiratory volume (FEV_1) All results were compared with a control group (10 men mean(s.d.) age 34 (9) years).

This short course of IVN increased visceral proteins but not TBP However there was a 5–15 per cent increase in respiratory function, which was maximal at 4 days This improvement is significant when compared with a total gain of only 10–25 per cent measured 200 days later after an 11 per cent gain in protein stores.

		Patients			
	Controls	Day 0	Day 7	Day 14	Day 200
TPB (kg)	11·3(0·6)	7·3(0·5)**	7·4(0·5)*	7·5(0·5)*	8·6(0·4)**(**)
RMS (cmH_2O)	104 (10)	65 (8)**	76 (9)§	78 (10)*	90 (9)†(†)
FEV_1 (litres)	4·0(0·3)	3·0(0·2)**	3·2(0·2)§	3·3(0·2)*	3·4(0·2)*(‡)

Values are mean(s.e.m.). TBP, total body protein; RMS, respiratory muscle strength; FEV_1, forced expiratory volume. Difference from previous measurement (final difference from control values). * n.s., † $P<0{\cdot}05$, § $P<0{\cdot}005$, ** $P<0{\cdot}0005$, Student's paired t test

These data suggest that depleted patients awaiting major surgery may benefit from 4–7 days IVN.

1. Windor JA, Hill GL. Risk factors for postoperative pneumonia *Ann Surg* 1988; **208**: 209–14.

Effects of supplemental arginine on wound healing

J.V. Reynolds, S. Richardson, J. Black and J.M. Daly (introduced by M.P. Brady), *Departments of Surgery and Orthopaedics, University of Pennsylvania, Philadelphia, USA*

Protein calorie malnutrition (PCM) impairs normal wound healing. Full nutritional repletion can restore healing to normal, but specific substrates may suffice. The aim of this study was to determine if the anabolic amino acid arginine (Arg)[1] could limit the adverse effects of PCM on wound healing. Adult male Fisher rats (250–300 g; $n=96$) were randomized to receive a 24 per cent or 2·5 per cent protein diet for 14 days before wounding with an 8 cm dorsal cutaneous incision After wounding, rats were randomized to continue on their existing diet or to receive 1 per cent Arg or isonitrogenous 1·7 per cent glycine (Gly) supplementation in addition to their existing diet. On days 14 and 21 after wounding, eight rats in each group were killed and 6 cm skin strips (five/rat) perpendicular to the wound axis were tested for wound bursting strength (WBS) using an MTS dynamic material tensiometer. The results are shown in the *Table*

Group		Wt change (g/day)		WBS (N)	
Before wounding	After wounding	Day 14	Day 21	Day 14	Day 21
24%	24%	1·3(4)	0·9(5)	16(4)	29(8)
24%	+Gly	1·3(0·5)	0·8(0·4)	16(5)	27(5)
24%	+Arg	1·4(0·2)	1·1(0·5)	17(5)	31(7)
2·5%	2·5%	−1·5(0·4)	−0·9(0·4)	13(1)	18(1)
2·5%	+Gly	−1·2(0·3)	−0·7(0·5)	13(2)	21(2)
2·5%	+Arg	−1·4(0·2)	−0·5(0·5)	15(3)	26(3)*

Values are mean(s.e.m.). *$P=0{\cdot}008$ Arg *versus* 2·5 per cent +Gly; $P<0{\cdot}001$ Arg *versus* 2·5 per cent

Supplementay dietary Arg significantly increased WBS at day 21 in protein-malnourished rats compared with both Gly and non-supplemented groups. These data suggest that Arg may have a role in the management of malnourished surgical patients at risk of wound failure.

Effect of fibrin glue on the mechanical properties of healing wounds

D.J. Byrne, J.C. Hardy, R.A.B. Wood, R. MacIntosh and A. Cuschieri, *Department of Surgery, Ninewells Hospital, Dundee and Protein Fractionation Centre, Scottish National Blood Transfusion Service, Edinburgh, UK*

Fibrin-based glues have a wide range of uses in surgical practice. Currently available commercial fibrin glues are not guaranteed to be free of viral particles and have varying concentrations of fibrinogen, thrombin and factor XIII In developing a safe fibrin glue, various formulations with differing fibrinogen, thrombin and factor XIII concentrations were tested on the healing of full thickness skin incisions in male Wistar rats closed with tape alone, or tape and glue.

Rats were killed at 4 and 8 days, wounds were excised and frozen at −70°C until testing. After thawing, multiple strips from the wounds were tested to rupture on an Instron tensiometer and stress and elastic modulus measured. The results showed that for a fibrinogen concentration of 39 g/l, wounds at 8 days had significantly higher mean(s.d.) stress values (52(10) g/mm^2) compared with control wounds (35(8) g/mm^2). However for a fibrinogen concentration of 58 g/l wounds were significantly weaker (26(10) g/mm^2) than controls The same pattern was seen with varying thrombin concentrations. A thrombin level of 200–600 units/ml gave significantly stronger wounds than both control wounds and wounds with a thrombin concentration of 1000 units/ml. These latter wounds in turn were weaker than control wounds. Similar experimens with factor XIII indicate that no additional factor XIII (on top of the native factor XIII already present) is necessary for adequate glue function Added factor XIII does not function in the same way as native factor XIII of a similar concentration.

We conclude that formulation of fibrin glue must be carefully performed as so to enhance and not inhibit wound healing.

Increased morbidity with abnormal pulmonary albumin flux in septic adult respiratory distress syndrome

K. Byrne, P.D. Carey, J.L. Tatum, M. Crossland, T. Barnes, J.I. Hirsch, J.A. Thompson, D.A. Henry, J. Young, H.J. Sugerman (introduced by W.A. Tanner), *Departments of Surgery, Medicine, Radiology and Biostatistics, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia, USA*

Damage to the pulmonary capillary membrane can be elicited by a rising lung:heart ratio (expressed as Slope Index (SI × 10^{-3} min^{-1})) of intravenous ^{99m}technetium-labelled albumin measured with a γ camera. Thirty patients with septic adult respiratory distress syndrome (ARDS), 13 patients with congestive heart failure (CHF) and 32 controls (C) underwent comparative scintigraphic studies A sepsis score was calculated for ARDS patients. There was no significant difference between SI in the control (mean(s.d.). 0·14(0·4)) and CHF (mean(s.d): 0·25(0·8)) groups The ARDS patients had a higher ($P<0{\cdot}001$) SI (mean(s.d.): 0·89(0·5)) than either the control or CHF groups. In the ARDS group, 15 patients had a normal and 15 an abnormal SI. There were no differences in gas exchange parameters or mortality between ARDS patients with normal or abnormal SI Patients with abnormal SI required longer ($P<0{\cdot}01$) mechanical ventilation and hospitalization, spent longer in the intensive care unit (ICU) and had higher ($P<0{\cdot}05$) mean sepsis scores than patients with normal SI (see *Table*).

	Ventilator (days)	ICU (days)	Hospital (days)	Sepsis score
Normal SI	7 (1)	11 (1)	35 (5)	13·3 (1·2)
Abnormal SI	36 (5)*	67 (9)*	113 (20)*	19·6 (1·4)**

Values are mean(s d.). * $P<0{\cdot}01$, ** $P<0{\cdot}05$ abnormal *versus* normal SI

This technique successfully differentiated permeability from non-permeability oedema and predicted increased morbidity in a subgroup of septic ARDS patients with increased pulmonary capillary albumin flux.

Management of ingrowing toenail

Sir

I was surprised that the leading article by Murray (*Br J Surg* 1989; **76**: 883–4) did not mention 'soft tissue' operations for ingrowing toenail. The opinion that the skin rather than the nail is at fault is supported by evidence that the shape of the nail does not differ from that in age matched controls[1], both groups showing considerable variation in nail curvature and axis deviation. As the nail does not appear to be abnormal, operations have been devised to treat the soft tissue abnormality, aiming to give a better cosmetic and functional result.

Radical excision of the nailfold, as described by Antrum[2], gave an 80 per cent cure rate. Subsequently, in a controlled trial, it produced only two recurrences in 32 treated toes[3]. This operation is quick and simple to perform, and does not disturb the nail or nail bed. It is very suitable for use by junior surgical trainees, to whom toenail surgery is often delegated. Its only disadvantage is that full healing takes an average of 5 weeks. The cosmetic result is excellent – indistinguishable from a normal toe.

Pelviureteric junction obstruction

Sir

We read with interest the paper by H. C. Ward and R. J. Brereton (*Br J Surg* 1989; **76**: 818–9) and would agree with their advice concerning the diagnostic use of ultrasound or intravenous urography. It should be stressed, however, that in this group of children the pelviureteric junction obstruction is intermittent and therefore demonstration of a hydronephrosis without a dilated ureter is most likely during an attack of pain. In practice many such children are under out-patient review and may come to investigation during periods of well being. In order not to miss the diagnosis in these children we would recommend requesting an ultrasound or intravenous urogram with a diuretic challenge.

Aids to the diagnosis of acute appendicitis

Sir

The diligent review by Hoffmann and Rasmussen (*Br J Surg* 1989; **76**: 774–9) of a difficult clinical area (where opinion has often substituted for observed fact) is warmly to be welcomed.

Whilst we are not qualified to discuss all diagnostic modalities from extensive first-hand experience, as regards computer-aided decision support the comments seem to us both fair and well-founded. For example, as regards cost we have long argued it makes little sense to acquire a large expensive computer solely for decision support, despite resultant savings. (Fortunately nowadays, this is not necessary; most units have a small personal computer or access to a patient administration system)

Perhaps we may be permitted one or two further comments, first concerning computer accuracy. It is correct to say 90 per cent is achievable – several centres have attained this figure, not just in the UK[1,2]. However, although all modalities are to some extent operator-dependent, the computer is alone in relying on data provided by the doctor. Provided with incomplete or ineptly-elicited clinical data, the computer's accuracy may be no greater than that of the unaided clinician.

The corollary of this point is crucial. As the computer is dependent upon clinical data, its presence acts both as a stimulus towards 'doing it right' and as a valuable training aid for young inexperienced surgeons, whose own performance improves to match that of the computer's[3] In this it stands alone amongst the 'investigative' modalities

Thus the ultimate place of computer prediction may not be as an isolated investigation but as an educational tool and a prelude to selecting, in appropriate cases, more expensive and more invasive investigations. Readers may be interested to know the European Community has recently launched a 'concerted action' involving 10 000 patients (in over 50 EC hospitals) to explore further this important topic. Nevertheless, the review's central theme is important and, on the available evidence, correct. In the age where several effective modalities are available, the old yardsticks no longer apply. A negative appendicectomy rate of 30 per cent (still prevalent in many centres) is no longer necessary and no longer acceptable In this day and age (where audit is *de rigeur*) it behoves all surgeons to check their own unit performance figures Where these are outwith (now) acceptable values, (and rates below 20 per cent are now readily and reproducibly attainable[3]) surgeons should clearly take action, but starting, we suggest, with insistence upon the highest standards of patient interview and physical examination.

Stapled ileal J pouch–anal anastomosis

Sir

We would like to reply to the letter from W. A Kmiot, K Hosie and M. R. B Keighley (*Br J Surg* 1989; **76**: 989) We described a technique of ileoanal pouch construction which involves eversion of the lower rectum to place the distal purse-string for the anal anastomosis (*Br J Surg* 1989; **76**: 350–1). Your correspondents are worried that this technique may lead to incontinence.

We would point out that when the rectum is fully mobilized down to the pelvic floor it can be everted without even minor dilatation of the anal canal. It should be emphasized that meticulous and obsessive dissection of the rectum is absolutely essential. With this method we have found that the postoperative resting and squeeze pressures of the anal musculature show no change from the values obtained before the operation. Although we understand the reservations expressed in the letter, in practice, even minor incontinence has not been a problem in the patients treated by this technique.

Biliary anatomy

Sir

It is always mildly flattering to have one's own work quoted and it was kind of McQuillan *et al.* (*Br J Surg* 1989; **76**: 696–8) to refer to our paper on biliary anatomy[1]. It is, however, extremely irritating to be misrepresented. Page and I did not specifically refer to the subvesical duct of Luschka though we did describe cholecystohepatic ducts. We most certainly did *not* advocate attempting to repair ducts of this minute size. Indeed it would be a fatuous *tour de force* of technical expertise to even try to do so! I have previously indicated in correspondence with the Journal that such fine filamentous ducts are not infrequently unrecognized at the time of cholecystectomy. Many may well be diathermied or suture ligated and in those few which are unrecognized, and which drain for a while after operation, no harm seems to come to the patient. The more substantial accessory hepatic ducts need recognizing at operation and must be carefully avoided.

Benign non-traumatic inflammatory strictures of the extrahepatic biliary system

Sir

We were interested to read the paper by Standfield *et al* (*Br J Surg* 1989; **76**: 849–52) on benign extrahepatic strictures without characteristic features of sclerosing cholangitis. The authors may have overlooked our paper[1] describing six patients with a similar condition which we christened 'proliferative cholangitis' because of the predominant histological feature of intramural bile duct proliferation, the radiological appearances of which may be diagnostic. Standfield *et al.* noted similar epithelial changes although they may not have been as remarkable. They saw chronic inflammation and ulceration in almost all patients and such features were also noted in some of ours. We may both have described the same or a very similar condition with a spectrum of histological abnormality and we doubt whether it is as uncommon as the scarcity of reports suggests.

Book reviews

Current Gastroenterology. Volume 8

G. Gitnick. 233 × 160 mm. Pp. 431. 1988 Illustrated. Chicago· Year Book Medical Publications. £53.50.

In the preface of this volume it is suggested that the 12 chapters are all written by experts in their field. With the exception of two chapters from Bologna the remaining experts are all North American. The text is written in the American rather than in the English language, e g. gastroenterologic The chapters vary in size and approach; some are written like a standard text book clearly representing the didactic views of an experienced clinician whereas others are reviews with brief comments on many topics and usually accompanied by vast numbers of references.

The chapter on endoscopy is well written and enjoyable, particularly the author's view of the future. The section on percutaneous endoscopic gastrostomy made interesting reading. In the large chapter on small bowel disease the North American experience in patients suffering from AIDS is well documented. The chapter on the colon is very much in keeping with British opinions although there was a startling statement that: '... current guidelines suggest that all patients over 35 years should have yearly haemoccult tests and 3-yearly flexible sigmoidoscopy'; the logistical and financial implications of that statement would have major consequences In the chapter on the pancreas there is an excellent section on the vexatious problem of idiopathic acute pancreatitis.

The topic of when to operate in patients with acute necrotizing pancreatitis is discussed but the three papers quoted are dated. The remaining chapters are devoted to the oesophagus, stomach, gastrointestinal hormones, gastrointestinal cancer, nutritional aspects of gastroenterology, imaging of the abdomen and two verbose chapters on inflammatory bowel disease which could have readily been condensed into a single chapter.

Gastroesophageal Reflux

G Jamieson, A Duranceau. 230 × 160 mm. Pp 281. Illustrated. 1988 Philadelphia. W. B. Saunders. £31.00

This book is a joint production from Montreal and Adelaide and all contributors bar one are surgeons It is extremely well produced and I found the chapters on diagnostic aspects of gastro-oesophageal reflux particularly helpful. A logical scheme is proposed taking into account the large number of ways of documenting gastro-oesophageal reflux ending up with 24 h ambulatory pH monitoring. It is a particularly valuable source of references on each topic and includes some excellent historical references going back for instance to the observations of Quincke in 1879 and Hertz in 1910 on the pathogenesis of gastro-oesophageal reflux disease.

Some of the rather confusing aspects of reflux disease such as the association with globus and the mythical Schatzki ring are fully and comprehensively discussed Needless to say there will be deficiencies in any book and I thought the Nissen fundoplication was rather lightly described given the fact that it is the world-wide standard antireflux operation. At the end of this section on antireflux surgery I was unclear what the Editors thought was the correct way of performing this operation or even what they thought were the important variables in determining success. The book, however, remains a useful guide to the understanding of gastro-oesophageal reflux and I would recommend it particularly to surgeons who deal with this disease and especially for those who have a research interest in it.

Biliary Lithotripsy

J. T. Ferrucci, M. Delius, H. J. Burhenne. 260 × 185 mm. Pp. 309 Illustrated. 1989. London· Wolfe Medical Publications. £61 00.

Cholecystectomy is at present being assailed by 'non-invasive' procedures for gallstone clearance, such as, extracorporeal lithotripsy and dissolution therapy, as well as 'minimally invasive' methods, including percutaneous stone dissolution or mechanical extraction. This book does not stay within the confines of its title but reviews all these latest techniques. It is a distillate of the first International Symposium on Biliary Lithotripsy, held in July 1988

The book gives a good overview of the subject as it was in July 1988. It starts with a discussion of the science behind shockwaves, the action of different lithotripters and their effects on gallstones and soft tissues. Next, there are a number of reports from various authors, giving their experiences with extracorporeal lithotripsy. These vary from the wide experience of the pioneering Munich group to those with much less experience. Further subjects tackled include sections on the natural history of gallstones, their dissolution and the prevention of recurrence. Some experience using lithotripsy for bile duct stones is given, while the section assessing the technology, the market, and the future has a distinct North American flavour Finally, there are presentations by seven manufacturers of extracorporeal lithotripters describing the specifications of their machines. This section might be helpful for prospective buyers, although the best type of lithotripter for gallstones remains undecided.

For those who wish to embark on this form of therapy, this book, which is well produced, would be very useful If, however, your interest is more casual, then it may be cheaper to obtain reprints of about half a dozen seminal papers on the subject.

Year Book of Surgery 1988

S. I. Schwartz, O. Jonasson, E. Peacock, G. Shires, F. Spencer, J Thompson. 235 × 255 mm. Pp. 483 Illustrated 1988. Chicago. Year Book Medical Publishers Inc £38.00

The Year Book of Surgery is one of a series of over three dozen volumes published each year to cover the whole field of medicine. The volume on surgery has 27 chapters covering a wide spectrum of general surgery but including trauma, burns, transplants and cardiac surgery. Each chapter consists of some two dozen abstracted papers considered by the editors to be the most interesting or significant publications of the year 1987. Each abstracted paper is then followed by editorial comment which I find by far the most interesting feature of the book. The editors are American and have consulted 70 journals to make their selection. There is a fair balance between publications on each side of the Atlantic. This is a book for the post fellowship reader as there is rather more emphasis on rare but challenging surgical problems, such as medullary carcinoma of thyroid and pylorus preserving pancreatoduodenectomy, papers on everyday problems of hernias, piles, and varicose veins were not reviewed. Were there no significant contributions in 1987?

At the beginning is an annual overview where the contents of each chapter are skilfully summarized. As we all now have to specialize it is useful to have this overview of what is happening outside our own fields. At the end there is a good subject and author index. Is this a book for the general surgeon who just cannot keep up with journals? Yes and no. It certainly drew my attention to good articles that I should not have overlooked in British journals but the choice of papers reviewed is so personal to individual sub-editors that there cannot be comprehensive coverage. Dr Schwartz and his team have put in a massive amount of work to produce the volume and time will not be wasted reading sections of the book, but it is one for the library rather than personal bookshelves.

Scientific Foundation of Surgery. 4th ed.

J. Kyle, L. C. Carey. 285 × 215 mm. Pp. 651. Illustrated. 1989. London: Heineman Medical Books. £75.00.

Shortly after his retirement from the Chair of Surgery in Liverpool in 1963, Charles Wells conceived the idea of providing surgeons, both trainee and established, with a comprehensive text describing the scientific and physiological basis of surgery. That such a book was long needed was undoubted and, with his colleague, James Kyle, he produced the eminently successful first edition of Scientific Foundations of Surgery. In addition, Charles Wells had identified a yawning gap in the clinical literature, because it became quickly evident that many other clinical disciplines also lacked an appropriate monograph on the scientific basis of their discipline. As a result, an entire series of scientific foundation books were published over the succeeding years.

This fourth edition, published in the year in which Professor Wells died, brings the surgeon up-to-date with scientific advances in surgery at the end of the 1980s. The success of this book is assured by the continuing editorship of James Kyle of Aberdeen who has been joined by Dr Larry Carey of Columbus, Ohio. The value of the book lies not only in the clear exposition of the basic sciences of surgery, but also the ability of the Editors to ensure that the contributors identified and described the clinical relevance of surgical physiology and pathophysiology. In 59 chapters, the 85 contributors have revised or rewritten much of the text. Opportunity has been taken to include many recent developments. Many chapters are excellent: the new chapter on imaging is a model of its kind.

Not surprisingly in a book of this size there is some unevenness of treatment and a need for stricter editorial control. For example, there has been recently considerable interest in anorectal function and the clinical measurements which are necessary in patients with distressing faecal incontinence. The writer of this chapter should have been given more space to discuss the mechanisms of faecal continence and to describe the methods currently used for its diagnosis and treatment. The entire complex problem of portal hypertension and bleeding oesophageal varices is ignored, the only reference to the portal vein being contained in one short paragraph in an anatomical section in the chapter on the pancreas. I could find no reference to the pathophysiology of oedema or ascites, nor to the mode of action of modern diuretics which play an important part in the care of the critically ill. Nevertheless, the chapter on shock syndrome and intensive care and acute renal failure should be required reading of all surgical trainees.

Almost 20 years after the launch of the first edition, this book will, during the 1990s, meet the requirements of surgical trainees taking examinations in the UK. The new regulations for the Fellowship of the Royal Colleges relate the basic sciences to clinical surgery very much more closely than hitherto. Charles Wells was a strong protagonist of a close linking of examinations in the basic sciences with those in surgery in general; indeed the book had been launched with that end in view. At last events are catching up with his prescience and, without doubt, this book and its successive editions will become the classic text for the young surgeon.

Kidney Transplantation, Principles and Practice. 3rd ed.

P J Morris. 235 × 155 mm. Pp. 788 Illustrated. 1988. Philadelphia. W B Saunders. £56.50.

Renal transplantation is now firmly established as the optimal treatment for the vast majority of patients with end-stage renal failure. This book is aimed at all of those involved in the care of patients undergoing renal transplantation – an objective which the two previous editions have achieved with great success as shown by their international popularity. In this new edition, Professor Morris has drawn together contributions from physicians, surgeons and scientists based in North America, Europe and Australasia. Most of the chapters from the previous edition have been extensively revised, updated, and in many cases completely rewritten and several new chapters have been added. The result is an expanded edition which comprehensively covers all aspects of renal transplantation, both established and new Despite the large number of contributing authors, the 30 chapters which make up this edition are well integrated and of even quality The book is uniformly well illustrated and all chapters are extensively referenced, for example the chapter on Cyclosporine contains well over 200 references.

Progress in renal transplantation has been based largely on scientific discovery rather than technical advances and this is reflected in the content of many of the chapters. For example, there are excellent reviews on the immunology of graft rejection, the experimental background to specific unresponsiveness, HLA matching and crossmatching and on aspects of renal preservation before transplantation. At a clinical level, the medical and surgical aspects of dialysis and transplantation are all covered, including a thorough description of transplantation in children. The surgical techniques of vascular access and renal transplantation are clearly outlined and the evaluation of the living related and the cadaver kidney donor is discussed together with the operation of donor nephrectomy. Also included is an update on technical aspects of the increasingly common practice of harvesting kidneys from multiorgan cadaveric donors.

Graft rejection remains the major problem following renal transplantation and a notable feature of this new edition is the increased coverage given to immunosuppression – six chapters in all. Together, these describe current views on this crucial and often controversial area. There are also informative chapters on the prevention and management of the other complications which may occur after transplantation, including technical, infective and cardiovascular problems The editor has identified and included several new chapters of particular relevance to contemporary practice. For example, the diabetic with renal failure, and renal transplantation in the developing world are each addressed with the special problems which may be encountered in these two situations highlighted. In the final chapter, the editor reviews the overall results of renal transplantation in the management of end-stage renal failure. The improvement in graft survival continues and the current results of transplantation are now very good. Nevertheless, as pointed out, there is no room for complacency and, in particular, there is still considerable scope for improving the long term prospects of patients after transplantation Hopefully, with the current pace of discovery it may not be too long before the scientific advances presently taking place are translated into clinical practice.

This new edition of 'Kidney Transplantation' will ensure its continued position as the outstanding single volume on renal transplantation and as such it is unrivalled and therefore highly recommended for anyone who is involved in the care of patients undergoing renal transplantation.

Concise System of Orthopaedics and Fractures

A Graham Apley, L. Solomon. 235 × 165 mm. Pp. 300. Illustrated. 1988. London Butterworths. £14.95.

This book is an offshoot of the larger Apley's system of orthopaedics and fractures which has been a standard and extremely popular text book of orthopaedics since it was first published in 1959. To a large extent the format of general orthopaedics, regional orthopaedics, fractures and joint injuries follows the original text book The feel of the book is generally the same as its larger predecessor and many of the excellent diagrams are repeated The text has however been completely rewritten and certainly achieves its aim of expanding the principles of the subject. The book is therefore aimed at undergraduate students and junior doctors together with those important members of the allied professions. Although concise it is not a short book with some 330 pages in all and despite its paper cover is still too heavy to carry in a medical coat. The book like its predecessor is beautifully styled and I am sure will rapidly gain affection with the readership to whom it is aimed. I would be disappointed, however, if it were to supercede the System of Orthopaedics and Fractures which has for so long been a stalwart of British postgraduate orthopaedic training.

Vascular Birthmarks. Hemangiomas and Malformations

J. B. Mulliken, A. E Young. 265 × 190 mm. Pp. 483. Illustrated. 1988. Philadelphia: W. B. Saunders. £98.00.

This beautifully produced and well illustrated volume has been edited and written by two surgeons, as they themselves put it; 'one from Old England and one from New England'. The book is written with the New English spelling and has multiple contributors Four major sections make up the volume. The first section consists of a chapter on 'Vascular Birthmarks in Folklore, History, Art and Literature' which is both informative and entertaining and includes many illustrations of individuals who have some connection with vascular birthmarks These individuals range from Cicero who apparently had a vascular anomaly below his left eye, to the present day General Secretary of the Soviet Union. There follows an article by John Mulliken on the classification of vascular birthmarks. This area is controversial and the literature surrounding it is very confusing. Problems in classification are fully discussed and the author of this chapter finally recommends a separation of vascular birthmarks into hemangiomas (commonly not present at birth) and vascular malformations ('by definition' present at birth). It is stated however that 'arteriovenous anomalies' can first appear later in childhood and the early adult period and it is unclear as to whether the authors regard these as hemangiomas or malformations.

The arrangement of the following sections of the book follows the separation into hemangiomas and malformations, and pathogenesis, diagnosis and treatment are considered. The final section of the book is entitled 'Problems and Solutions' and includes articles on regional vascular malformations and assorted other contributions including chapters on the therapeutic techniques of laser therapy and embolization and a final chapter on the emotional impact of a vascular birthmark. In the preface the authors state that the stimulus to write this book was a series of meetings of the International Workshop for the study of Vascular Anomalies. The overall structure of the book rather reflects this and although there has obviously been some careful editing there is still some degree of overlap between the various chapters. Despite this and occasional errors (a glomus tumour is referred to as a hemangiopericytoma, and generalized essential telangiectasia is given as a synonym for angioma serpiginosum), there is much useful new and beautifully illustrated material present in this volume in addition to a well referenced and up-to-date bibliography. The authors intend their book to be a reference for both primary and secondary care physicians and surgeons. 'Vascular Birthmarks' can be warmly recommended not only to these groups but to anyone with an interest in this common and fascinating group of conditions.

An Illustrated Guide to Gastrointestinal Motility

D. Kumar, S Gustavsson. 255 × 195 mm. Pp. 470. Illustrated. 1988. Chichester John Wiley and Sons £65.00

Gastrointestinal motility was once the Cinderella of clinical science, rarely represented in general surgical and gastroenterological endeavour. At the upper end of the gastrointestinal tract the dominant interest was in peptic ulcer, and the effects of acid and pepsin in the stomach and oesophagus carried much more weight with surgeons Distally there had always been a small group interested in the problem of diverticular disease and related motility problems, but the part in between, the entire mid-gut area, was more or less inaccessible before the advent of 30 years of telemetering capsules At first the use of these was difficult and the results somewhat uncertain but with time more reliable techniques have evolved and taped records make possible longer study periods. With the gradual disappearance of peptic ulcer as a surgical disease there is more scope for the surgeon investigating the motor abnormalities of the upper and lower GI tract. Nowhere has this become more apparent than in the colorectal area, all the more so because of the increasing impact of the bowel problems of an ageing population.

The construction of this book is good in content and follows a logical pattern in that it moves from cells and tissues to the motility of normal organs, including sphincters, and then to clinical problems. It includes much about computers in motility assessment and evaluation It has a certain modern attractiveness and is simple and explicit about what can often daunt the novice to this field who may have to use sophisticated apparatus with a day-to-day language different from that in clinical work The methods outlined consider the excitability of cells, the electrical patterns of events and tissues and the means of achieving the pressures which in turn make the end-stage phenomena of such transit happen, and which in turn are studied by radiological and isotope methods as 'organ events' which illuminate function.

To the reviewer the book was a stimulating record of what contemporary knowledge now is in this field. There are magisterial accounts by Christensen, Devroede, Janssen, Vantrappen and Phillips and all the London Hospital contributors who form one-sixth of the entire list of contributions which is surely a great tribute to the growth of gastrointestinal motility science in the Departments of Norman Williams and David Wingate. It can be recommended to all who are interested in this field and is a must for all gastroenterologically-minded surgeons.

General Thoracic Surgery. 3rd ed.

T. W Shields, 290 × 220 mm. Pp. 1251. Illustrated. 1989 Beckenham Lea and Febiger. £100.00.

The third edition of 'General Thoracic Surgery' weighs-in at 3·65 kg. Dr Shields has succeeded in what must have been a monumental task of coordinating the contributions of 115 authors and although I have not read every one of the 1222 pages of text, there seems little duplication of effort. Each chapter deals with one particular aspect of thoracic disease and is generously illustrated with black and white photographs. The X-ray films chosen to depict particular aspects of chest disease have reproduced well, and my only disappointment was the poor quality of some illustrations of operative details.

As one would expect from such a book, it proceeds in sections from anatomy, physiology and imaging to a systematic review of diseases affecting the various structures of the thoracic cage excluding the heart. The journey takes the reader via diagnostic procedures, pre-, peri- and postoperative management, operative procedures and thoracic trauma Each chapter concludes with references and suggestions for further reading.

Of the sections and chapters I particulary enjoyed reading were those on 'Preanaesthetic evaluation and preparation' and on 'The conduct of anaesthesia' both of which were masterly descriptions of the optimum care for patients undergoing thoracic surgery, and which have important lessons for surgeons and anaesthetists involved not only with thoracic surgery but in the general surgical management of more elderly patients. The paragraph on 'informed consent' struck a sensible balance between providing enough information and unduly alarming the patient, but did make the point that the essence of such discussions should be documented – a lesson we should be adopting much more rigorously for all major surgical procedures. I was also delighted to learn that Dr Fogarty's balloon catheter can be used as a bronchial blocker, being positioned accurately under direct vision with a fiberoptic bronchoscope.

The illustrations in the new chapters on computerized tomography and nuclear magnetic resonance imaging of the thorax reveal very clearly the value of these techniques in clarifying the nature and extent of intrathoracic pathology.

Having spent some time wrestling with inhaled foreign bodies in the past it was salutory to be reminded of the value of careful preparation: 'If 2 h are spent in preparation, the safe endoscopic removal of a foreign body may take only 2 min. But if only 2 min are taken for preparation, the endoscopist may find himself attempting ineffective, makeshift procedures for the next frustrating 2 h' A lesson that applies to many aspects of surgical practice!

Although not a book for every surgeon's bookshelf, medical libraries without a modern text on thoracic surgery can do no better than obtain a copy of this splendid book.

Liposuction Surgery and Autologous Fat Transplantation

S. Asken. 290 × 210 mm Pp. 166. Illustrated. 1988. East Norwalk Appleton and Lange. £117.70.

It is inevitable that a new surgical technique will find an enthusiast to write a book about it. Liposuction's brief history began with such a disaster in 1929 (the amputation of a leg of a dancer due to a vascular injury) that the next report of its use was not until 1968. By 1982 there were enough interested surgeons to form a Liposuction Society in America. Although the author of this book is a cosmetic surgeon, and most of the indications and results described belong in this category, it does deserve evaluation since it has the potential to fill other needs.

After a chapter on the basic structure and metabolism of fat, which is just acceptable, there is a chapter on the physics of suction which is inadequate. He is on stronger ground describing indications for liposuction and the equipment. He is on less secure ground on the initial consultation and follow-up techniques; having seen the consent form, I can only admire the persistence of the patients who still want to have this procedure done.

As in most plastic and cosmetic surgery books, the series of before and after photographs show attractive results but give little clue to the reliability and reproducibility of these techniques. Clearly this is a technique that needs to be learnt by practical experience which is not readily conveyed on the pages of a book. A major defect is the absence of any critical appraisal of the outcome in the patients who have had either liposuction or autologous fat transplantation, in which section a more critical appraisal of the fate of the transplanted fat would have been welcome. Overall, I am unable to recommend this book as it is insufficiently critical to allow me to be persuaded as to the value of the techniques described, nor is this a subject which lends itself to being learned from a book.

Lasers in Medicine – An Introductory Guide; 2nd ed.

G. T. Absten, S. N. Joffe. 215 × 135 mm. Pp. 71. Illustrated. 1988. London Chapman and Hall. £7.95.

This small book is an attempt to summarize the use of lasers in medical practice for physicians and surgeons unfamiliar with the effect of laser light on tissue. The book contains introductory chapters on laser physics, the laser–tissue interaction and descriptions of the individual lasers, and finishes with a short chapter on laser safety. The rest of the book contains short descriptions of the uses of lasers in various specialties; there are now 14 of these and the list is still growing. All of these chapters are well-written and accurate; in particular the authors explain the physics well and rightly stress the importance of a good delivery system coupled to the correct laser for a particular application. There are, however, some problems. The whole point of a book on laser applications in medicine is to explain how and why different wavelengths are chosen for different applications, such an explanation is lacking and the reader is left trying to bridge for himself the gap between the physics and the clinical application. Some errors are perpetrated. These include the myth that it is possible to focus light from a Nd-YAG laser within tissue, it is too highly scattered for this. There are also some statements on the use of the Nd-YAG laser in cutting tissue during general surgical operations which are at variance with the literature. There is considerable emphasis on the use of sapphire fibretips with a delivery system for the Nd-YAG laser and such emphasis is misplaced until there is more evidence to show how or indeed whether these devices are an improvement on other delivery systems. The bibliography is very general and somewhat repetitive in nature; a few references to the many definitive review articles which now exist within the specialties would have been helpful. In general this book does give the general reader an introduction to lasers in medicine but further reading will be essential for a proper grasp of the subject.

Cancer Chemotherapy: An Introduction. 3rd ed.

T J. Priestman. 235 × 155 mm Pp. 209 Illustrated 1989. London Springer–Verlag £19 50.

This is an easy book to read, an excellent introduction to the subject and should be mandatory reading for all surgeons involved in the treatment of cancer patients so that they have a working knowledge of the place of different treatments in the overall management of their patients Dr Priestman gives a very honest approach to the limitations of cancer chemotherapy but at the same time points out its efficacy in those tumours that are sensitive to drug therapy.

Section one opens with an excellent chapter on the 'Principles of tumour growth'. Section two deals only with 'Biological response modifiers' This whole section comprises only six pages. As much work is being undertaken in this field, I would have expected more on this subject. There is little mention of immunotherapy. The chapter on biological response modifiers should have been expanded. Section three on the 'Principles of endocrine therapy' is excellent. The 'Clinical role of chemotherapy' is covered in the last four chapters to varying degrees. Those sensitive tumours are naturally covered more comprehensively. Haematological cancers are covered in much greater detail than solid tumours which are encountered more frequently by surgeons. Dr Priestman has been very direct about the place of drug treatment in solid tumours and the section on 'Carcinoma of the breast' gives a balanced opinion. The use of intraperitoneal chemotherapy and regional perfusion of different organs except limbs has sadly not been covered.

In his chapter on 'The place of chemotherapy in cancer treatment', he points out that unfortunately cancers curable with chemotherapy form only a small proportion, less than 10 per cent, of all malignant tumours, and the older, perhaps less glamorous, modalities of surgery and radiotherapy still account for the greater majority of cancer cures today. I do not think my surgical and radiotherapy colleagues find their treatment of cancer less glamorous, and in fact in my opinion, they are much more so than medical oncology!

I would highly recommend this book for undergraduate students, as it deals with a difficult subject for them crisply and clearly.

Aids to Postgraduate Surgery

R. M. Watkins, J. M. Thomas. 215 × 135 mm. Pp 300. Not illustrated. 1989. Singapore Churchill Livingstone. £8 95.

'This nuggety book of surgical information. (a) aims to appraise the relative merits of various forms of management; (b) gives recent developments and current controversies, (c) is mainly for the FRCS; (d) is in note format, and is irritatingly verbless.'

The book is clearly popular, is full of useful basic information on selected topics, but falls short of its stated claims. 'Most surgeons prefer to treat hyperthyroidism by surgery' will surprise few, but it is not a serious contribution. The management of bleeding varices contains all the options in various conformations, but has no clear flow of decisions. It leaves out the big message – surgery kills 'C's – and includes a host of interruptions or shunt procedures, mostly of nostalgic interest.

There is a real muddle in oesophageal carcinoma, carefully defined by UICC criteria, then expanded to include obstructing gastric cancers at the cardia. Many series do the same, but .... Surgical options mentioned do not include the common upper partial gastrectomy through the left chest, nor the increasingly popular pull through Alas, there is no mention of the floppy Nissen, nodal dissection in gastric cancer, or medical management of stomal ulcer. The new sections are good, but can one face an examiner (or patient) without a comment on gallstone lithotripsy? I would have liked to see sections on benign breast problems, anal conditions, gynaecological emergencies, day surgery, and audit, rather than Zollinger-Ellison syndrome and radical therapy for carcinoma of the pancreas.

The book is soft-back, useful as a crammer, but not a required library purchase.

Hernia

L M. Nyhus, R. E. Condon. 260 × 185 mm. Pp. 764 Illustrated. 1989. London. Gower Medical Publishing. £49.50.

Now in its third edition, this book has a well earned place as the standard reference for surgeons interested in any aspect of abdominal wall or diaphragmatic hernias. The text is a delightful mix of anatomy, history and well-balanced didactics from 85 contributors. The first three chapters include a historical survey and a general description of the anatomy of the inguinal region. Contributors writing later chapters on clinical aspects of groin hernia have each given their version of the anatomy, which consolidates the perspective, but sometimes provides an interesting conflict, e.g the exact origins and strength of the iliopubic tract are hotly debated. Nevertheless, several authors admit there is a spectrum of structural variation to be found in the groin of patients with hernias; consequently repair should be tailored to take account of the structures present. Wantz writing about the 'Canadian repair' (Shouldice technique) believes that all inguinal hernias can be repaired by a single method, except indirect hernias in young patients and repeated recurrences.

Prosthetic materials are given a good airing, so much so that in the preface the Editors caution against the wave of enthusiasm which is currently sweeping the surgical world regarding its use in hernia problems. Nevertheless, Condon states that he inserts a prosthesis to reinforce a hiatal hernia repair in every instance. Certainly many surgeons may feel that the natural tissues are adequate for use in antireflux procedures. A technique that has not found popularity amongst British surgeons, the pre-peritoneal approach, is described in three sections with an enlightening and well-illustrated contribution by Stoppa. As a reference text the surgeon will not find a better book to refer to if he wishes to discover more about such rare hernias as Richters and Littres, Spigelian hernia, supravesical or sciatic hernia and many others. Several chapters are devoted to diaphragmatic hernia and reflux peptic oesophagitis with authoritative contributions from Hill, Orringer, DeMeester and others. The standard layout in each section is a historical over-view, with some discussion of the anatomy and outcome for the technique described. The result is a very authorative and well balanced treatment of the subject which will enable the surgeon to refer to the text for help in handling even the most difficult hernia in adults or in children. Finally, there is a short, but helpful section on medico legal aspects of hernia which applies to American law, but has an important message for all in our current climate of escalating litigation. The so called 'compensable' hernia sustained while working, and the subject of ischaemic orchitis resulting from herniorrhaphy of the groin are well discussed. Inevitably, one can find a few blemishes in this otherwise excellent book, and to me these were the outdated and rather unclear line drawings in a few chapters, the puzzling absence of a member of the Shouldice Clinic to contribute the chapter on the 'Canadian repair', the failure to discuss the work of Jenkinson apropos incisional hernia, and the largely obsolete descriptions of repair of sliding inguinal hernias by reperitonealization.

This book can be highly recommended as a comprehensive operative manual, a reference book and a historical survey of hernia repair this century. For these reasons the third edition will become the standard work for hernia surgeons.

Gray's Anatomy. 37th ed.

P. L. Williams, R. Warwick, M. Dyson, L. H. Bannister. 305 × 235 mm. Pp 1598. Illustrated. 1989. Edinburgh: Churchill Livingstone. £70.00.

Gray's Anatomy must be internationally the best known text book in the whole field of Medicine. This year we see the 37th edition (appearing only 9 years after the 36th) in its 131 years of distinguished existence: this, in spite of terrible book reviews of the 1st edition in *The Lancet* and in the *British Medical Journal*! The present Gray is very different in its format, size and much of its content to the war time edition that myself and my contemporaries cut our anatomical teeth upon. It is, of course, now so large and heavy that it can for the most part be regarded only as a book of reference. I use it to obtain the ultimate truth when my students argue with me about terminology or when an unresolved problem crops up in the dissecting room – and under these circumstances it never lets me down. The modern Gray proves that anatomy is not as dry as dust but is a living subject. There are magnificently illustrated sections on evolution, cellular anatomy and embryology. However, the bulk of Gray remains the detailed mapping of the human body. But here, in addition to conventional excellent illustrations of macroscopic topographical anatomy, together with its authoritative text, there is also complementary radiology, computerized tomography, conventional histology and electron microscopy.

At the extremely cheap price of £70 00, representing about five pence a page, today's Gray's Anatomy can only be described as the medical bargain of the year.

Common Problems in Gastrointestinal Surgery

J. Fischer. 240 × 155 mm Pp. 451. Illustrated 1989. Chicago Year Book Medical Inc. £36.00

This book is part of the series 'Common Problems in Surgery' edited by Richard F. Kempczinski and consists of 58 chapters each devoted to a defined clinical problem. Surprisingly the remit of gastrointestinal surgery includes chapters on problems of the breast, thymus, lung and thyroid gland.

The concept of this series is to present the personal views of distinguished surgeons on a specific clinical problem with an emphasis on practical surgical management. In general the 58 authors (all from North America except two from the UK) succeed in this task aided by occasional interjections by the Editor As a result a reader can, in 10–15 min, obtain a specialized and authoritative opinion on the practical management of a particular problem

In practice each author usually manages to give a good overview of the clinical subject so that unconventional views are easily placed in perspective. There are six main sections in the book. The sections on the upper gastrointestinal tract and trauma are probably the most interesting whilst the section on small and large intestine is probably of less interest. It is a book best read in short sections and should be enjoyed by surgeons of all grades. It is best kept on a surgical ward

Renal Transplantation. 1st ed.

E. L. Milford 235 × 155 mm. Pp 293 Illustrated 1989. Churchill Livingstone. £50.00

This is a curious book. It is American, which does not help in making it readable and relevant, but that is not the problem. It is one of a series, entitled 'Contemporary Issues in Nephrology', and the Preface indicates that it is written for and by clinicians – including nephrologists, urologists and transplantation specialists. Yet its content is strangely removed from clinical practice. There is the paradox that the book tells you exactly how many microlitres of rabbit serum to use in the cytotoxic cross match before transplantation, but not how many milligrams of cyclosporin to give the patient afterwards. There is very little surgical detail, yet the chapter on surgical complications tells you how to approach and manage a transplant renal artery stenosis but not how to avoid it.

The book does contain much information, with many chapters comprehensively referenced (although already slightly out of date) and there is great detail in the chapters describing the immunological background to transplantation and the immune response. Somehow it does not hang together in a particularly well organized way and the overall book is considerably less useful than the sum of its parts It is not a major reference book, but many of the chapters would nonetheless make worthwhile reading for surgeons interested in renal transplantation

Subject index

Abdomen

Abdominal aortic aneurysms: a review of current problems, 826
Abdominal pain: a surgical audit of 1190 emergency admissions, 1121
Clinical decisions and laparoscopy *versus* computer prediction in the management of the acute abdomen, 1011
Surgical significance of the bile duct of Luschka, 696
Ten-year review of non-ruptured aortic aneurysms, 1251

Abdominal

Surgical significance of the bile duct of Luschka, 696
Ten-year review of non-ruptured aortic aneurysms, 1251

Abscess

Intraperitoneal rupture of amoebic liver abscess, 202

Achalasia

Heller's myotomy with partial fundoplication (surgical workshop), 99
Primary disorders of oesophageal motility, 1111
Pseudoachalasia after radical gastrectomy (case report), 97

Acid

Anterior lesser curvature laser seromyotomy with posterior truncal vagotomy: a potential treatment of peptic ulcer disease, 949
Sham feeding for testing gastric secretory capacities before and after parietal cell vagotomy, 946

Adhesion

Reduced human peritoneal plasminogen activating activity: possible mechanisms of adhesion formation, 382

Amputation

Major amputation in a defined population: incidence, mortality and results of treatment, 308
Rehabilitation after lower limb amputation: a comparative study of above-knee, through-knee and Gritti-Stokes amputations, 622

Anastomosis

An improved technique of J pouch construction and ileoanal anastomosis (surgical workshop), 350
Anastomotic aneurysms of the femoral artery: aetiology and treatment, 1014
Anastomotic leakage: an avoidable complication of Lewis–Tanner oesophagectomy, 127
Collagen changes around intestinal anastomoses in germ-free rats, 797
Continuous single-layer gastrointestinal anastomosis: a prospective audit, 493
Effect of mechanical bowel preparation on anastomotic integrity following low anterior resection in dogs, 756
Sutureless large bowel anastomosis: European experience with the biofragmentable anastomosis ring, 344

Anatomy

Number and anatomical distribution of incompetent thigh perforating veins, 581
Surgical anatomy of the human spleen, 198

Aneurysm

Abdominal aortic aneurysm repair in the over eighties, 1018
Abdominal aortic aneurysms: a review of current problems, 826
Anastomotic aneurysms of the femoral artery: aetiology and treatment, 1014
General practice-based population screening for abdominal aortic aneurysms: a pilot study, 479
Risk of aortic aneurysm surgery as assessed by preoperative gated heart pool scan, 26
Subclavian aneurysm: a presentation of Takayusu's arteritis (case report), 1031
Surgical significance of the bile duct of Luschka, 696
Ten-year review of non-ruptured aortic aneurysms, 1251
Ultrasonographic screening of the abdominal aorta among siblings of patients with abdominal aortic aneurysms, 589

Angioplasty

Intervention for graft stenoses: the role of surgery and transluminal angioplasty (short note), 1017
Laser angioplasty with a pulsed NdYAG laser: early clinical experience, 921
Role for prazosin in reducing the development of rabbit intimal hyperplasia after endothelial denudation, 936

Antibiotic

Relationship between bile colonization, high-risk factors and postoperative sepsis in patients undergoing biliary tract operations while receiving a prophylactic antibiotic, 374
Timing of prophylactic antibiotics in abdominal surgery: trial of a pre-operative *versus* an intra-operative first dose, 52

Anticoagulant

Perioperative anticoagulant control, 1107

Anus

A study of the physiological variation in anal manometry, 69
Air-filled microballoon manometry for use in anorectal physiology, 72
Anal canal mucosa in restorative proctocolectomy for ulcerative colitis, 970
Anal endosonography in the evaluation of perianal sepsis and fistula *in ano*, 752
Anal and ileal pouch manometric measurements before ileostomy closure are related to functional outcome after ileal pouch–anal anastomosis, 613
Anorectal function after abdominal rectopexy: parameters of predictive value in identifying return of continence, 64
Anorectal physiology measurement: report of a working party, 356
Anorectal physiology validated: a repeatability study of the motor and sensory tests of anorectal function, 607
Anterior sphincter plication and levatorplasty in the treatment of faecal incontinence, 1058
Comparison of digital and manometric assessment of anal sphincter function, 973
Construction of a neorectum and neoanal sphincter following previous proctocolectomy, 1191
Critical assessment of the quality of continence after postnatal repair for faecal incontinence, 1054
Effect of anterior resection on anal sphincter function, 783
External and internal anal sphincter responses to rectal distension in normal subjects and in patients with idiopathic faecal incontinence, 617
Function after ileal pouch and stapled pouch–anal anastomosis for ulcerative colitis, 1168
Idiopathic constipation associated with impaired urethrovesical and sacral reflex function, 748
Lateral internal sphincterotomy in the treatment of fourth degree haemorrhoids, 1181
Long term results of anorectal myectomy for chronic constipation, 1163
Non-condylomatous perianal disease in homosexual men, 1064
Paget's disease of the anus: a clinicopathological study, 60
Podophyllin *versus* scissor excision in the treatment of perianal condylomata acuminata: a prospective study, 1067
Psychiatric screening for patients with faecal incontinence or chronic constipation referred for surgical treatment, 352
Results of external sphincter repair in Crohn's disease, 959
Sequelae of internal sphincterotomy for chronic fissure *in ano*, 431
Squamous cell carcinoma of the anus at one hospital from 1948 to 1984, 806
Totally stapled abdominal restorative proctocolectomy, 961

Aorta

Abdominal aortic aneurysm repair in the over eighties, 1018
Abdominal aortic aneurysms: a review of current problems, 826
General practice-based population screening for abdominal aortic aneurysms: a pilot study, 479
Graft occlusion following aortofemoral bypass for peripheral ischaemia, 572
Risk of aortic aneurysm surgery as assessed by preoperative gated heart pool scan, 26
Surgical significance of the bile duct of Luschka, 696
Ten-year review of non-ruptured aortic aneurysms, 1251
Ultrasonographic screening of the abdominal aorta among siblings of patients with abdominal aortic aneurysms, 589

Appendix

Aids in the diagnosis of acute appendicitis, 774
Appendicectomy and carcinoma of the caecum, 1049
Appendicitis and appendicectomy in a Melanesian population, 368
Appendicitis complicating meconium ileus equivalent (case report), 168
Technique of laparoscopic appendicectomy (surgical workshop), 616

Apud

Liver transplantation for primary and secondary hepatic apudomas, 248

Arm

Acute ischaemia of the upper limb compared with acute lower limb ischaemia, a 5-year review, 515

Arterial

Free-flap reconstruction of heel pad after femorotibial bypass salvage graft (case report), 158

Artery

Acute ischaemia of the lower limb: the effect of centralizing vascular surgical services on morbidity and mortality, 592
Acute lower limb arterial ischaemia: a role for continuous oxygen inhalation, 1021
Arteriogram scoring systems and pulse generated run-off in the assessment of patients with critical ischaemia for femorodistal bypass, 1202
Choice of material for above-knee femoropopliteal bypass graft, 7
Crossover femoral grafting to allow subsequent donor limb angioplasty (surgical workshop), 307
Femorofemoral bypass in unilateral iliac artery occlusion, 22
Free-flap reconstruction of heel pad after femorotibial bypass salvage graft (case report), 158
Graft occlusion following aortofemoral bypass for peripheral ischaemia, 572
Intervention for graft stenoses: the role of surgery and transluminal angioplasty (short note), 1017
Operative assessment of femorodistal bypass grafts using a new Doppler flowmeter, 925

Index

Plasma eicosanoids, platelet function and cold sensitivity, 401
Role of B-mode venous mapping in infrainguinal *in situ* vein–arterial bypasses, 305
Role for prazosin in reducing the development of rabbit intimal hyperplasia after endothelial denudation, 936
Subclavian arteritis (case report, 824

Assessment

APACHE II score in a massive upper gastrointestinal haemorrhage from peptic ulcer prognostic value and potential clinical applications, 733
Risk of aortic aneurysm surgery as assessed by preoperative gated heart pool scan, 26
Value of a risk questionnaire in screening for colorectal neoplasm, 280

Atheroma

Intravenous digital subtraction angiography for extracranial carotid artery disease, 1247

Audit

Abdominal pain -a surgical audit of 1190 emergency admissions, 1121
Clinical and histological sequelae of Roux-en-Y diversion, 481
Editorial process at *The British Journal of Surgery*, 211
Extending surgical audit the assessment of postoperative outcome, 531
Operative mortality following surgery for colorectal cancer,.745
Surgical audit of patients undergoing common bile duct exploration for stone, 1136

Bacteriology

Relationship between bile colonization, high-risk factors and postoperative sepsis in patients undergoing biliary tract operations while receiving a prophylactic antibiotic, 374

Bile

Gallstone lithotripsy with the pulsed dye laser: *in vitro* studies, 457
Relationship between bile acid malabsorption using the ^{75}Se homocholic acid taurine scanning method and diarrhoea following right hemicolectomy (short note), 707

Bile duct

Benign non-traumatic inflammatory strictures of the extrahepatic biliary system, 849
Biliary leakage and peritonitis following removal of T tubes after bile duct exploration (short note), 1296
Combined internal and external biliary fistulae treated by percutaneous cholecystlithotomy (case report), 1258
Endoscopic palliation of malignant biliary obstruction in a child, 1092
Endoscopic endoprosthesis insertion following failure of cholecystojejunostomy in pancreatic carcinoma, 454
Endoscopic management of inoperable cholangiocarcinoma using iridium-192, 867
Endoscopic sphincterotomy for bile duct stones in patients with intact gallbladders, 856
Human fasting and postprandial sphincter of Oddi motility, 709
Intrahepatic stones, 213
^{99m}Tc-labelled HIDA scintigraphy in assessment of bile leakage after removal of T tube from the common bile duct (short note), 1319
Long-term follow-up after choledochojejunostomy for bile duct stones with complex clearance of the bile duct, 451
Measurement of body water compartments after ligation of the common bile duct in the rabbit, 461
Mirizzi syndrome and cholecystobiliary fistula a unifying classification, 1139
Pernasal catheter perfusion without dissolution agents following endoscopic sphincterotomy for common duct stones (short note), 410
Relationship between bile colonization, high-risk factors and postoperative sepsis in patients undergoing biliary tract operations while receiving a prophylactic antibiotic, 374
Surgical audit of patients undergoing common bile duct exploration for stone, 1136
Surgical options in traumatic injury to the extrahepatic biliary tract, 256
Surgical treatment of chronic pancreatic cholangiopathy, 1129
T tubes: a comparison of virgin, slit, guttered and sculpted designs (surgical workshop), 342
Technique for operative cholangiography after endoscopic sphincterotomy (surgical workshop), 571
Treatment of a postoperative cholycystocutaneous fistula by an endoscopic stent (case report), 159

Biopsy

Extended role for needle biopsy in the management of carcinoma of the breast, 553
Fibroadenoma of the breast· a follow-up of conservative management, 390
Role of fine needle aspiration cytology and computer tomography in the diagnosis of parotid swellings, 1273
Ultrasound guided percutaneous pancreatic biopsy (short note), 706

Blood

Blood transfusion in colorectal cancer (short note), 522
Differential effects of low-dosage tissue plasminogen activator and streptokinase on platelet aggregation, 1026
Perioperative anticoagulant control, 1107
Plasma eicosanoids, platelet function and cold sensitivity, 401
Surgery in patients, with von Willebrand's disease, 398
Surgical management of neutropenic enterocolitis, 821

Blood flow

Changes in the hepatic perfusion index during the development of experimental hepatic tumours, 259
Changes in vascularity of liver tumours after hepatic arterial embolization with degradable starch microspheres, 699
Operative assessment of femorodistal bypass grafts using a new Doppler flowmeter, 925
Vascularization of small liver metastases, 545

Breast – benign

Fibroadenoma of the breast a follow-up of conservative management, 390
Non-cyclical mastalgia an improved classification and treatment, 901

Breast – cancer

Salvage surgery for advanced local recurrence of breast cancer, 512

Breast – malignant

Additional value of fine-needle aspiration biopsy in a mammographic screening trial, 840
CA 15-3· its relationship to clinical stage and progression to metastatic disease in breast cancer, 838
Clinical, radiological and cytological diagnosis of breast cancer in young women, 835
Combined endocrine effects of LHRH agonist (Zoladex) and tamoxifen (Nolvadex) therapy in premenopausal women with breast cancer, 1262
Comparison of intracavitary bleomycin and talc for control of pleural effusions secondary to carcinoma of the breast, 1266
Extended role for needle biopsy in the management of carcinoma of the breast, 553
Factors influencing local recurrence after excision and radiotherapy for primary breast cancer, 890
Fibromatosis of the breast (case report), 1268
Follow-up after treatment of primary breast cancer, 187
Follow-up of two treatment modalities for ductal cancer *in situ* of the breast, 672
Lipids in breast carcinogenesis, 1069
Management of screen detected ductal carcinoma *in situ* of the female breast, 564
Omental transposition in the treatment of locally advanced and recurrent breast cancer, 559
Relationship between DNA ploidy and survival in patients with primary breast cancer, 830
Residual tumour after biopsy for non-palpable ductal carcinoma *in situ* of the breast, 185
Wide local excision as the sole primary treatment in elderly patients with carcinoma of the breast, 898

Breast – surgery

A simple specimen mount for the orientation of breast biopsies (surgical workshop), 312
Arm morbidity within a trial of mastectomy and either nodal sample with selective radiotherapy or axillary clearance, 568
Factors influencing local recurrence after excision and radiotherapy for primary breast cancer, 890
Follow-up after treatment of primary breast cancer, 187
Management of screen detected ductal carcinoma *in situ* of the female breast, 564
Omental transposition in the treatment of locally advanced and recurrent breast cancer, 559
Salvage surgery for advanced local recurrence of breast cancer, 512
Wide local excision as the sole primary treatment in elderly patients with carcinoma of the breast, 898

Breast – tumour

Characterization of breast cancer subgroups in an African population, 182
Ductal carcinoma *in situ* a new clinical problem, 660
Salvage surgery for advanced local recurrence of breast cancer, 512
Selection of patients for breast conservation, 885
Tamoxifen comes of age, 325

Carcinogenesis

Cholecystectomy and colorectal cancer, 250
Lipids in breast carcinogenesis, 1069

Carcinoma

Ductal carcinoma *in situ* a new clinical problem, 660
Gastrointestinal malignancy rationale for adjuvant therapy using early postoperative intraperitoneal chemotherapy, 1082
Leucine kinetics in surgical patients II a study of the effect of malignant disease and tumour burden, 509
Sister Mary Joseph's nodule a study of the incidence of biopsied umbilical secondary tumours in a defined population (short note), 728
Squamous cell carcinoma of the anus at one hospital from 1948 to 1984, 806

Carotid

Carotid body tumours and other cervical paragangliomas diagnosis and management in 25 patients, 33
Intraoperative internal carotid artery restenosis detected by transcranial Doppler monitoring (case report), 1315
Intravenous digital subtraction angiography for extracranial carotid artery disease, 1247

Catheter

Complications of intravenous feeding catheters, 15

Chemotherapy

Adjuvant therapy of poor prognosis colon cancer with levamisole· results of an EORTC double-blind randomized clinical trial, 284
Gastrointestinal malignancy rationale for adjuvant therapy using early postoperative intraperitoneal chemotherapy, 1082

Chest

Chylothorax and delayed paraparesis in an infant following improper use of a front seat belt (case report), 129

Comparison of intracavitary bleomycin and talc for control of pleural effusions secondary to carcinoma of the breast, 1266
Reconstruction of chest wall defects with homologous dura mater grafts (surgical workshop), 870

Claudication

Graft occlusion following aortofemoral bypass for peripheral ischaemia, 572

Coagulation

Perioperative anticoagulant control, 1107
Platelet aggregability after endoscopic intravariceal injection of 5 per cent ethanolamine oleate into oesophageal varices, 939
Surgery in patients with von Willebrand's disease, 398

Collagen

Collagen changes around intestinal anastomoses in germ-free rats, 797
Viscoelastic properties and collagen content of the long saphenous vein in normal and varicose veins, 37

Colon

Lower gastrointestinal bleeding, 3
Sigmoid volvulus in rural Ghana (short note), 737

Colon – benign

Adult intussusception in Glasgow, UK (short note), 727
Fatty tumours of the large intestine: a clinicopathological review of 13 cases, 793
Prognosis after surgery for colonic Crohn's disease, 1184

Colon – cancer

Blood transfusion in colorectal cancer (short note), 522
Effect of nutritional supplementation on protein synthesis in tumour and host tissues of rats with colonic cancer, 790

Colon – congenital

Juvenile polyp in an ileoanal J pouch following restorative proctocolectomy for juvenile polyposis coli, 801

Colon – inflammatory

Anal canal mucosa in restorative proctocolectomy for ulcerative colitis, 970
Colonic complications of severe acute pancreatitis, 362
Function after ileal pouch and stapled pouch–anal anastomosis for ulcerative colitis, 1168
Ileitis and pouchitis after colectomy for ulcerative colitis, 668
Localization of lower gastrointestinal bleeding using *in vivo* technetium-99m-labelled red blood, 358
Multivariate analysis of factors influencing the results of restorative proctocolectomy, 740
Restorative proctocolectomy is the first choice elective surgical treatment for ulcerative colitis, 1109
Surgical management of neutropenic enterocolitis, 821
Toxic megacolon and perforation caused by *Salmonella* (case report), 796

Colon – malignant

Obstructing carcinomas of the colon, 965
Prognostic value of nucleolar organizer regions and ploidy values in advanced colorectal cancer, 1152
Role of dietary restriction in Haemoccult screening for colorectal cancer, 976

Colon – surgery

An improved technique of J pouch construction and ileoanal anastomosis (surgical workshop), 350
Anal canal mucosa in restorative proctocolectomy for ulcerative colitis, 970
Anastomotic suture materials and implantation metastasis an experimental study, 331
Clinical and histological sequelae of Roux-en-Y diversion, 481
Clinical results of colectomy for severe constipation, 600
Colon interposition in children, 681
Compartment syndrome· a cautionary tale (case report), 1297
Conservative proctocolectomy a dubious option in ulcerative colitis, 738
Construction of a neorectum and neoanal sphincter following previous proctocolectomy, 1191
Délorme operation for prolapsed colostomy, 1321
Endoscopic balloon dilatation of colonic anastomotic strictures, 780
Experience of restorative proctocolectomy with ileal reservoir, 77
Familial polyposis. colon cancer in the absence of rectal polyps (case report), 744
Function after ileal pouch and stapled pouch–anal anastomosis for ulcerative colitis, 1168
Ileitis and pouchitis after colectomy for ulcerative colitis, 668
Intraoperative colonic irrigation in the treatment of acute sigmoid volvulus (short note), 957
Intussusception presenting as ileal reservoir ischaemia following restorative proctocolectomy (case report), 148
Juvenile polyp in an ileoanal J pouch following restorative proctocolectomy for juvenile polyposis coli, 801
Multivariate analysis of factors influencing the results of restorative proctocolectomy, 740
Obstructing carcinomas of the colon, 965
Operative mortality following surgery for colorectal cancer, 745
Proctocolectomy and ileoanal pouch anastomosis without conservation of a rectal muscular cuff, 273
Prognosis after surgery for colonic Crohn's disease, 1184
Quicker intraoperative colonic irrigation, 604
Relationship between bile acid malabsorption using the ^{75}Se homocholic acid taurine scanning method and diarrhoea following right hemicolectomy (short note), 707
Restorative proctocolectomy is the first choice elective surgical treatment for ulcerative colitis, 1109
Stapling technique for pouch–anal anastomosis without the need for purse-string sutures (surgical workshop), 348
Surgical treatment of carcinoma involving the vagina (surgical workshop), 816
Sutureless large bowel anastomosis. European experience with the biofragmentable anastomosis ring, 344
Totally stapled abdominal restorative proctocolectomy, 961
Treatment of cancer of the colon. a non-specialist's point of view, 71

Colon – tumour

Adjuvant therapy of poor prognosis colon cancer with levamisole: results of an EORTC double-blind randomized clinical trial, 284
Anastomotic suture materials and implantation metastasis· an experimental study, 331
Appendicectomy and carcinoma of the caecum, 1049
Cholecystectomy and colorectal cancer, 250
Detection of lymph node metastases in colorectal carcinoma before and after fat clearance, 1165
Familial polyposis. colon cancer in the absence of rectal polyps (case report), 744
Stapling technique for pouch–anal anastomosis without the need for purse-string sutures (surgical workshop), 348
Treatment of cancer of the colon. a non-specialist's point of view, 71
Value of a risk questionnaire in screening for colorectal neoplasm, 280

Complication

Anastomotic leakage: an avoidable complication of Lewis–Tanner oesophagectomy, 127
Clinical and histological sequelae of Roux-en-Y diversion, 481
Colonic complications of severe acute pancreatitis, 362
Complications of intravenous feeding, catheters, 15
Complications of parotid surgery the need for selectivity, 1034
Gastrocolic fistula as a complication of benign gastric ulcer· report of four cases and update of the literature, 1298
Long acting somatostatin analogue in dumping syndrome, 1294
Operative mortality following surgery for colorectal cancer, 745
Timing of strangulation in adult hernias, 725

Computer

Computer analysis in making preoperative decisions. a rational approach to lymph node dissection in gastric cancer patients, 905
Computer-aided diagnosis. a review, 82
Extending surgical audit the assessment of postoperative outcome, 531
Surgeons and computers, 1

Constipation

Clinical results of colectomy for severe constipation, 600
Long term reults of anorectal myectomy for chronic constipation, 1163

Crohn's disease

Prognosis after surgery for colonic Crohn's disease, 1184
Recurrence after strictureplasty or resection for Crohn's disease, 335
Results of external sphincter repair in Crohn's disease, 959
Ten-year experience of strictureplasty for obstructive Crohn's disease, 339

Cryotherapy

Cryotherapy for liver metastases: a new approach, 1040

Cytology

Clinical, radiological and cytological diagnosis of breast cancer in young women, 835
Sample size in fine needle aspiration biopsy, 1270

Deep vein thrombosis

Randomized study of adjusted *versus* low dose heparin prophylaxis of deep vein thrombosis in hip surgery, 933
Thigh length *versus* knee length stockings in the prevention of deep vein thrombosis, 296

Dermatology

Paget's disease of the anus a clinicopathological study, 60
Skin cancer in renal transplant recipients, 1002

Diagnosis

Aids in the diagnosis of acute appendicitis, 774
Clinical decisions and laparoscopy *versus* computer prediction in the management of the acute abdomen, 1011
Computer-aided diagnosis: a review, 82
Protein electrophoresis of diagnostic peritoneal lavage in penetrating abdominal trauma a marker of significant injury, 1308

Diaphragm

Congenital diaphragmatic hernia (case report), 1317

Diet

Lipids in breast carcinogenesis, 1069

Doppler

Arteriogram scoring systems and pulse generated run-off in the assessment of patients with critical ischaemia for femorodistal bypass, 1202
Operative assessment of femorodistal bypass grafts using a new Doppler flowmeter, 925
Role of B-mode venous mapping in infrainguinal *in situ* vein–arterial bypasses, 305

Saphenous vein in infrainguinal bypass (surgical workshop), 928

Drains
Bile leaks after simple cholecystectomy, 1046

Drug – side effects
Late perforation of a mediastinal oesophagocoloplasty (case report), 917

Duodenum
Changing pattern of admissions and operations for duodenal ulcer, 230
Human fasting and postprandial sphincter of Oddi motility, 709

Education
Attitudes of operating theatre staff to inoculation-risk cases, 195
Extending surgical audit: the assessment of postoperative outcome, 531
Technical training in surgery: the trainee's view, 1291
The development and evaluation of a clinical test of surgical resident proficiency, 982

Electrolyte balance
Measurement of body water compartments after ligation of the common bile duct in the rabbit, 461

Embolus
Acute ischaemia of the lower limb: the effect of centralizing vascular surgical services on morbidity and mortality, 592
Acute ischaemia of the upper limb compared with acute lower limb ischaemia, a 5-year review, 515
Adverse effects of preoperative hepatic artery chemoembolization for resectable hepatocellular carcinoma: a retrospective comparison of 138 liver resections, 871

Endocrine
Endocrine abstracts, 1094
Isotopic studies during surgical convalescence, 154
Long acting somatostatin analogue in dumping syndrome, 1294
Plasma arginine vasopressin levels and arterial pressure during open heart surgery, 29
Pre-treatment with octreotide as an adjuvant to surgical resection in Zollinger–Ellison syndrome (case report), 75
Somatostatin analogue SMS 201-995 (octreotide) as a possible solution to the dumping syndrome after gastrectomy or vagotomy, 140

Endoscopy
Controlled trial of heater probe treatment in bleeding peptic ulcers, 541
Endoluminal ultrasound for early detection of local recurrence of rectal cancer, 1176
Endoscope palliation of malignant biliary obstruction in a child, 1092
Endoscopic balloon dilatation of colonic anastomotic strictures, 780
Endoscopic endoprosthesis insertion following failure of cholecystojejunostomy in pancreatic carcinoma, 454
Endoscopic haemostatis for non-variceal upper gastrointestinal haemorrhage, 219
Endoscopic management of inoperable cholangiocarcinoma using iridium-192, 867
Endoscopic sphincterotomy for bile duct stones in patients with intact gallbladders, 856
Peptic pyloric stenosis treated by endoscopic balloon dilatation, 1147
Pernasal catheter perfusion without dissolution agents following endoscopic sphincterotomy for common duct stones (short note), 410
Platelet aggregability after endoscopic intravariceal injection of 5 per cent ethanolamine oleate into oesophageal varices, 939
Positioning the Verres needle (surgical workshop), 381
Rigid endoscopy under general anaesthesia is safe for chronic injection scleropathy, 719
Treatment of a postoperative cholycystocutaneous fistula by an endoscopic stent (case report), 159

Epidemiology
Appendicitis and appendicectomy in a Melanesian population, 368
Changing pattern of admissions and operations for duodenal ulcer, 230
Changing patterns in gastric adenocarcinoma, 914
Gastric cancer: a 25-year review, 535
Major amputation in a defined population: incidence, mortality and results of treatment, 308

Experimental
Attachment of indium-111 labelled endothelial cells to pretreated polytetrafluoroethylene vascular grafts, 1259
Collagen changes around intestinal anastomoses in germ-free rats, 797
Effect of mechanical bowel preparation on anastomotic integrity following low anterior resection in dogs, 756
Effects of somatostatin analogue (SMS 201-995) on the growth and development of hepatic tumour derived by intraportal injection of Walker cells in the rat, 1149
Protective effects of recombinant human tumour necrosis factor α and interferon γ against surgically simulated wound infection in mice, 1282
Three-dimensional morphological study of the pancreatic microvasculature in caerulein-induced experimental pancreatitis, 853
Use of a bioprosthesis to relieve tension in oesophageal anastomosis: an experimental study, 496

Femoral
Anastomotic aneurysms of the femoral artery: aetiology and treatment, 1014
Choice of material for above-knee femoropopliteal bypass graft, 7
Femorofemoral bypass in unilateral iliac artery occlusion, 22
Functional closure of the femoral canal revealed by computed tomographic scanning, 1195

Fistula
Acute pancreatitis and pancreatic fistula formation, 1126
Alkaline battery-induced tracheo-oesophageal fistula (case report), 1045
Combined internal and external biliary fistulae treated by percutaneous cholecystlithotomy (case report), 1258
Congenital tracheo-oesophageal fistula in an adult (case report), 412
High-output external fistulae of the small bowel: management with continuous enteral nutrition, 676
Mirizzi syndrome and cholecystobiliary fistula: a unifying classification, 1139
Sequelae of internal sphincterotomy for chronic fissure *in ano*, 431

Foot
Risk factors in onychocryptosis, 45

Gallbladder
Bile leaks after simple cholecystectomy, 1046

Gallbladder – benign
Endoscopic sphincterotomy for bile duct stones in patients with intact gallbladders, 856

Gallbladder – inflammatory
Mirizzi syndrome and cholecystobiliary fistula: a unifying classification, 1139
Role of cholecystectomy in the management of critically ill patients suffering from acute cholecystitis, 693

Gallbladder – surgery
Bile leaks after simple cholecystectomy, 1046
Cholecystectomy and colorectal cancer, 250
^{99m}Tc-labelled HIDA scintigraphy in assessment of bile leakage after removal of T tube from the common bile duct (short note), 1319
Role of cholecystectomy in the management of critically ill patients suffering from acute cholecystitis, 693
Surgical options in traumatic injury to the extrahepatic biliary tract, 256
Technique for operative cholangiography after endoscopic sphincterotomy (surgical workshop), 571

Gallbladder – tumour
Gallbladder carcinoma: role of radiation therapy, 448

Gallstones
Anergy in patients with biliary lithiasis, 169
Gallstone lithotripsy with the pulsed dye laser: *in vitro* studies, 457
Intrahepatic stones, 213
Long-term follow-up after choledochojejunostomy for bile duct stones with complex clearance of the bile duct, 451
Surgical audit of patients undergoing common bile duct exploration for stone, 1136

Gastrointestinal
Endoscopic haemostasis for non-variceal upper gastrointestinal haemorrhage, 219
Repeat selective visceral angiography in patients with gastrointestinal bleeding of obscure origin, 226

Gastrointestinal disease
Yersinia infections in surgical practice, 499

Gastro-oesophageal junction
A prospective randomized trial of Angelchik prosthesis *versus* Nissen fundoplication, 86
Cardia carcinoma considered as a distinct clinical entity, 136
Determinants of gastro-oesophageal reflux and their inter-relationships, 241
Oesophageal transit of marshmallow after the Angelchik procedure, 245

Geriatric
Abdominal aortic aneurysm repair in the over eighties, 1018
Operative mortality after perforated peptic ulcer (short note), 521
Wide local excision as the sole primary treatment in elderly patients with carcinoma of the breast, 898

Graft
Attachment of indium-111 labelled endothelial cells to pretreated polytetrafluoroethylene vascular grafts, 1259
Choice of material for above-knee femoropopliteal bypass graft, 7
Crossover femoral grafting to allow subsequent donor limb angioplasty (surgical workshop), 307
^{111}In-labelled leucocyte imaging in vascular graft infection, 41
New way to take pinch grafts (surgical workshop), 1093
Reconstruction of chest wall defects with homologous dura mater grafts (surgical workshop), 870
Salvage of an exposed arterial prosthesis by tissue expansion (case report), 1320

Haemorrhage
A perspective for the management of variceal bleeding, 323
APACHE II score in a massive upper gastrointestinal haemorrhage from peptic ulcer: prognostic value and potential clinical applications, 733
Controlled trial of heater probe treatment in bleeding peptic ulcers, 541
Endoscopic haemostasis for non-variceal upper gastrointestinal haemorrhage, 219
Haemorrhage in pancreatic disease, 863

Localization of lower gastrointestinal bleeding using *in vivo* technetium-99m-labelled red blood, 358
Lower gastrointestinal bleeding, 3
Prediction of outcome in patients with acute variceal haemorrhage, 123
Repeat selective visceral angiography in patients with gastrointestinal bleeding of obscure origin, 226
Surgery in patients with von Willebrand's disease, 398

Hand

Delayed recovery of hand grip strength predicts postoperative morbidity following major vascular surgery, 704

Heart

Plasma arginine vasopressin levels and arterial pressure during open heart surgery, 29

Heredity

Familial polyposis colon cancer in the absence of rectal polyps (case report), 744
Recessive mutations and chromasome deletions leading to cancer, 327

Hernia

A prospective randomized trial of Angelchik prosthesis *versus* Nissen fundoplication, 86
Ambulatory hernia surgery, 1228
Congenital diaphragmatic hernia (case report), 1317
Early prediction of late incisional hernias (short note), 953
Expanded polytetrafluoroethylene patch for the repair of large abdominal wall defects, 803
Functional closure of the femoral canal revealed by computed tomographic scanning, 1195
Out-patient operation of inguinal hernia in children, 406
Timing of strangulation in adult hernias, 725

Hip

Randomized study of adjusted *versus* fixed low dose heparin prophylaxis of deep vein thrombosis in hip surgery, 933

Hydatid

Combination chemotherapy is more effective in postspillage prophylaxis for hydatid disease than either albendazole or praziquantel alone (short note), 954

Hyperplasia

Role for prazosin in reducing the development of rabbit intimal hyperplasia after endothelial denudation, 936

Hypertension

A perspective for the management of variceal bleeding, 323

Ileal pouch

An improved technique of J-pouch construction and ileoanal anastomosis (surgical workshop), 350
Anal and ileal-pouch manometric measurements before ileostomy closure are related to functional outcome after ileal pouch–anal anastomosis, 613
Experience of restorative proctocolectomy with ileal reservoir, 77
Ileitis and pouchitis after colectomy for ulcerative colitis, 668
Intussusception presenting as ileal reservoir ischaemia following restorative proctocolectomy (case report), 148
Juvenile polyp in an ileoanal J pouch following restorative proctocolectomy for juvenile polyposis coli, 801
Proctocolectomy and ileoanal pouch anastomosis without conservation of a rectal muscular cuff, 273

Imaging

Additional value of fine-needle aspiration biopsy in a mammographic screening trial, 840
Alcohol sclerotherapy of non-parasitic cysts of the liver, 254
Anal endosonography in the evaluation of perianal sepsis and fistula *in ano*, 752
Arteriogram scoring systems and pulse generated run-off in the assessment of patients with critical ischaemia for femorodistal bypass, 1202
Bile leaks after simple cholecystectomy, 1046
Clinical, radiological and cytological diagnosis of breast cancer in young women, 835
Contrast enhanced CT scan as a diagnostic procedure in mesenteric ischaemia due to mesenteric venous thrombosis (short note), 93
Contrast-enhanced abdominal computed tomography scanning and prediction of severity of acute pancreatitis a prospective study, 268
Functional closure of the femoral canal revealed by computed tomographic scanning, 1195
^{111}In-labelled leucocyte imaging in vascular graft infection, 41
Intravenous digital subtraction angiography for extracranial carotid artery disease, 1247
^{99m}Tc-labelled HIDA scintigraphy in assessment of bile leakage after removal of T tube from the common bile duct (short note), 1319
Laparoscopy, ultrasound and computed tomography in cancer of the oesophagus and gastric cardia. prospective comparison for detecting intra-abdominal metastases, 1036
Localization of lower gastrointestinal bleeding using *in vivo* technetium-99m-labelled red blood, 358
Medullary carcinoma of the thyroid management of persistent hypercalcitonaemia utilizing [^{99m}Tc](v)dimercaptosuccinic acid scintigraphy, 1278
Minimally invasive surgery for the retrieval of complex fractured double J stents (surgical workshop), 680
New radionucleotide method of visualizing subclavian vein occlusion following temporary venous access (short note), 1024
Prospective comparison of preoperative imaging and intraoperative ultrasonography in the detection of liver tumours, 1323
Relationship between bile acid malabsorption using the ^{75}Se homocholic acid taurine scanning method and diarrhoea following right hemicolectomy (short note), 707
Repeat selective visceral angiography in patients with gastrointestinal bleeding of obscure origin, 226
Role of fine needle aspiration cytology and computer tomography in the diagnosis of parotid swellings, 1273
Saphenous vein in infrainguinal bypass (surgical workshop), 928
Technique for operative cholangiography after endoscopic sphincterotomy (surgical workshop), 571
Ultrasound guided percutaneous pancreatic biopsy (short note), 706

Immune system

C-reactive protein, antiproteases and complement factors as objective markers of severity in acute pancreatitis, 177
Effect of nutritional status on acute phase protein response to elective surgery, 165
Protective effects of recombinant human tumour necrosis factor α and interferon γ against surgically simulated wound infection in mice, 1282
Reticuloendothelial failure in chronic intra-abdominal sepsis the role of opsonic fibronectin, 161
Tumour necrosis factor and bacterial sepsis, 670

Incision

Early prediction of late incisional hernias (short note), 953
Expanded polytetrafluoroethylene patch for the repair of large abdominal wall defects, 803

Incontinence

Anorectal function after abdominal rectopexy parameters of predictive value in identifying return of continence, 64
Anterior sphincter plication and levatorplasty in the treatment of faecal incontinence, 1058
Critical assessment of the quality of continence after postnatal repair for faecal incontinence, 1054
Effect of anterior resection on anal sphincter function 783
External and internal anal sphincter responses to rectal distension in normal subjects and in patients with idiopathic faecal incontinence, 617
Psychiatric screening for patients with faecal incontinence or chronic constipation referred for surgical treatment, 352

Infection

Attitudes of operating theatre staff to inoculation-risk cases, 195
^{111}In-labelled leucocyte imaging in vascular graft infection, 41
Management of infection after prosthetic abdominal rectopexy (Wells' procedure), 610
Metabolic response to sepsis and trauma, 115
Need for surgical wound dressing, 204
Postsplenectomy sepsis, 1074
Protective effects of recombinant human tumour necrosis factor α and interferon γ against surgically simulated wound infection in mice, 1282
Reticuloendothelial failure in chronic intra-abdominal sepsis: the role of opsonic fibronectin, 161
Superior mesenteric vein thrombosis caused by *Yersinia pseudotuberculosis* (case report), 272
Timing of prophylactic antibiotics in abdominal surgery trial of a pre-operative *versus* an intra-operative first dose, 52
Toxic megacolon and perforation caused by *Salmonella* (case report), 796
Tumour necrosis factor and bacterial sepsis, 670
Typhoid perforation, 887
Yersinia infections in surgical practice, 499

Inflammation

Subclavian arteritis (case report), 824

Interventional radiology

Alcohol sclerotherapy of non-parisitic cysts of the liver, 254
Changes in vascularity of liver tumours after hepatic arterial embolization with degradable starch microspheres, 699
Endoscopic balloon dilatation of colonic anastomotic strictures, 780
Management of pancreatic pseudocysts, 550

Intestinal

Adult intussusception in Glasgow, UK (short note), 727
Appendicitis complicating meconium ileus equivalent (case report), 168
High-output external fistulae of the small bowel management with continuous enteral nutrition, 676
Superior mesenteric vein thrombosis caused by *Yersinia pseudotuberculosis* (case report), 272
Ten-year experience of strictureplasty for obstructive Crohn's disease, 339
Typhoid perforation, 887

Intussusception

Adult intussusception in Glasgow, UK (short note), 727
Intussusception presenting as ileal reservoir ischaemia following restorative proctocolectomy (case report), 148

Ischaemia

Acute ischaemia of the lower limb. the effect of centralizing vascular surgical services on morbidity and mortality, 592
Acute ischaemia of the upper limb compared with acute lower limb ischaemia, a 5-year review, 515
Acute lower limb arterial ischaemia. a role for continuous oxygen inhalation, 1021
Contrast enhanced CT scan as a diagnostic procedure in mesenteric ischaemia due to mesenteric venous thrombosis (short note), 93

Ischaemic strictures in patients treated with a low anterior resection and perioperative radiotherapy for rectal carcinoma, 605
Postoperative gastric ischaemia, 844

Islet Cell

Diurnal insulin and glucose profiles following transplantation of fresh and cryopreserved canine pancreatic islets, 1287

Jaundice

Benign non-traumatic inflammatory strictures of the extrahepatic biliary system, 849
Endoscopic endoprosthesis insertion following failure of cholecystojejunostomy in pancreatic carcinoma, 454
Measurement of body water compartments after ligation of the common bile duct in the rabbit, 461

Kidney

Acute pancreatitis after renal transplantation, 1132
Changing concepts in renovascular surgery, 429
Pelviureteric junction obstruction and recurrent abdominal pain in childhood, 818
Reducing renal injury during transplantation, 999

Laparoscope

Clinical decisions and laparoscopy *versus* computer prediction in the management of the acute abdomen, 1011
Laparoscopy, ultrasound and computed tomography in cancer of the oesophagus and gastric cardia prospective comparison for detecting intra-abdominal metastases, 1036
Technique of laparoscopic appendicectomy (surgical workshop), 616

Laser

Anterior lesser curvature laser seromyotomy with posterior truncal vagotomy. a potential treatment of peptic ulcer disease, 949
Gallstone lithotripsy with the pulsed dye laser *in vitro* studies, 457
Laser angioplasty with a pulsed NdYAG laser. early clinical experience, 921
Low power interstitial NdYAG laser photocoagulation studies in a transplantable fibrosarcoma, 378
NdYAG laser treatment in the palliation of advanced oesophageal malignancy (short note), 912

Leg

Lower limb vein trauma: a long-term clinical and physiological assessment, 585
Acute lower limb arterial ischaemia a role for continuous oxygen inhalation, 1021

Liver – congenital

Alcohol sclerotherapy of non-parasitic cysts of the liver, 254

Liver – infection

Intraperitoneal rupture of amoebic liver abscess, 202

Liver – inflammatory

Intrahepatic stones, 213
Mesoatrial shunt a surgical option in the management of the Budd–Chiari syndrome, 474

Liver – malignant

Changes in the hepatic perfusion index during the development of experimental hepatic tumours, 259

Liver – surgery

A new solution for liver preservation, 107
Adverse effects of preoperative hepatic artery chemoembolization for resectable hepatocellular carcinoma. a retrospective comparison of 138 liver resections, 871
Hepatic tumour resection with profound hypothermia and circulatory arrest (case report), 548
Mesoatrial shunt a surgical option in the management of the Budd–Chiari syndrome, 474
Resectability of large focal liver lesions, 1042

Liver – tumour

Adverse effects of preoperative hepatic artery chemoembolization for resectable hepatocellular carcinoma. a retrospective comparison of 138 liver resections, 871
Changes in vascularity of liver tumours after hepatic arterial embolization with degradable starch microspheres, 699
Cryotherapy for liver metastases: a new approach, 1040
Effects of somatostatin analogue (SMS 201-995) on the growth and development of hepatic tumour derived by intraportal injection of Walker cells in the rat, 1149
Hepatic tumour resection with profound hypothermia and circulatory arrest (case report), 548
Liver transplantation for primary and secondary hepatic apudomas, 248
Palliative treatment of hepatic tumours, 771
Prospective comparison of preoperative imaging and intraoperative ultrasonography in the detection of liver tumours, 1323
Resectability of large focal liver lesions, 1042
Vascularization of small liver metastases, 545

Lymph system – inflammatory

Chylothorax and delayed paraparesis in an infant following improper use of a front seat belt (case report), 129

Lymph system – tumour

Contralateral inguinal lymph node metastasis in patients with melanoma of the lower extremities, 1161
Intra-abdominal lymphangiomas, 485
Sister Mary Joseph's nodule a study of the incidence of biopsied umbilical secondary tumours in a defined population (short note), 728
Thyroid lymphoma, 895

Malignant melanoma

Contralateral inguinal lymph node metastasis in patients with melanoma of the lower extremeties, 1161
Differential diagnosis of subungual melanoma from a surgical point of view, 1156
Malignant melanoma a plague of our times, 995

Management

Need for surgical wound dressing, 204
Surgical management of neutropenic enterocolitis, 821

Manometry

Air-filled microballoon manometry for use in anorectal physiology, 72
Anal and ileal pouch manometric measurements before ileostomy closure are related to functional outcome after ileal pouch–anal anastomosis, 613
Anorectal physiology measurement: report of a working party, 356
Determinants of gastro-oesophageal reflux and their inter-relationships, 241
Oesophageal transit of marshmallow after the Angelchik procedure, 245
Pancreatic duct pressure, duct permeablity and acute pancreatitis, 859

Measurement

Comparison of digital and manometric assessment of anal sphincter function, 973
Direct method of measuring venous ulcers (surgical workshop), 689

Metabolic

Anergy in patients with biliary lithiasis, 169
Branched chain amino acids as the protein component of parenteral nutrition in cancer cachexia, 149
Isotopic studies during surgical convalescence, 154
Leucine kinetics in surgical patients I a study of the effect of surgical 'stress', 505
Leucine kinetics in surgical patients II. a study of the effect of malignant disease and tumour burden, 509
Metabolic response to sepsis and trauma, 115
Plasma arginine vasopressin levels and arterial pressure during open heart surgery, 29

Monoclonal antibody

CA 15-3: its relationship to clinical stage and progression to metastatic disease in breast cancer, 838
Intraoperative immunostaining for detection of invasive cells at the resection margin of Borrmann type 4 gastric carcinoma using monoclonal antibody S202, 690

Morbidity

Complications of parotid surgery. the need for selectivity, 1034
Delayed recovery of hand grip strength predicts postoperative morbidity following major vascular surgery, 704

Motility

Delayed return of gastric emptying after gastroenterostomy, 145
Primary disorders of oesophageal motility, 1111
Somatostatin analogue SMS 201–995 (octreotide) as a possible solution to the dumping syndrome after gastrectomy or vagotomy, 140

Nail

Conservative treatment of ingrowing toenails, 955
Management of ingrowing toenail, 883
Phenol cauterization for ingrowing toenails: a review of five years' experience (short note), 598

Neck

Carotid body tumours and other cervical paragangliomas: diagnosis and management in 25 patients, 33

Neurological

Compartment syndrome a cautionary tale (case report), 1297

Nutrition

Branched chain amino acids as the protein component of parenteral nutrition in cancer cachexia, 149
Effect of nutritional status on acute phase protein resonse to elective surgery, 165
Effect of nutritional supplementation on protein synthesis in tumour and host tissues of rats with colonic cancer, 790
High-output external fistulae of the small bowel. management with continuous enteral nutrition, 676

Obesity

Biliopancretic bypass in the Prader–Willi syndrome (case report), 313
Gastric banding in the treatment of morbid obesity, 490
Gastroplasty for morbid obesity technique, complications and results in 60 cases, 131

Obstruction

Innominate vein compression syndrome (case report), 575
Obstructing carcinomas of the colon, 965
Quicker intraoperative colonic irrigation, 604
The role of contrast radiography in presumed bowel obstruction, 1121

Occlusion

Femorofemoral bypass in unilateral iliac artery occlusion, 22

Oesophagus

Heller's myotomy with partial fundoplication (surgical workshop), 99
Rigid endoscopy under general anaesthesia is safe for chronic injection scleropathy, 719

Oesophagus – congenital

Congenital tracheo-oesophageal fistula in an adult (case report), 412

Oesophagus – inflammation

A prospective randomized trial of Angelchik prosthesis *versus* Nissen fundoplication, 86
Oesophageal transit of marshmallow after the Angelchik procedure, 245

Oesophagus – inflammatory

A prospective randomized trial of Angelchik prosthesis *versus* Nissen fundoplication, 86
Barrett's oesophagus, 997
Oesophageal transit of marshmallow after the Angelchik procedure, 245
Primary disorders of oesophageal motility, 1111

Oesophagus – malignant

NdYAG laser treatment in the palliation of advanced oesophageal malignancy (short note), 912

Oesophagus – surgery

Alkaline battery-induced tracheo-oesophageal fistula (case report), 1045
Anastomotic leakage: an avoidable complication of Lewis–Tanner oesophagectomy, 127
Colon interposition in children, 681
Emergency subtotal oesophagectomy, 918
Late perforation of a mediastinal oesophagocoloplasty (case report), 917
Total gastrectomy and oesophagojejunostomy with linear stapling devices, 909
Transabdominal gastro-oesophageal devascularization and oesophageal transection for bleeding oesophageal varices, 943
Use of a bioprosthesis to relieve tension in oesophageal anastomosis: an experimental study, 496

Oesophagus – tumour

Clinicopathologic study of early stage oesophageal carcinoma, 759
Time-related changes in characteristics of prognostic significance in carcinomas of the oesophagus and cardia, 1301

Oncology

Anastomotic suture materials and implantation metastasis: an experimental study, 331
Changes in the hepatic perfusion index during the development of experimental hepatic tumours, 259
Effects of somatostatin analogue (SMS 201-995) on the growth and development of hepatic tumour derived by intraportal injection of Walker cells in the rat, 1149
Follow-up of two treatment modalities for ductal cancer *in situ* of the breast, 672
Low power interstitial NdYAGlaser photocoagulation: studies in a transplantable fibrosarcoma, 378
Prognostic value of nucleolar organizer regions and ploidy values in advanced colorectal cancer, 1152
Recessive mutations and chromosome deletions leading to cancer, 327
Relationship between DNA ploidy and survival in patients with primary breast cancer, 830
Skin cancer in renal transplant recipients, 1002
Splenectomy for massive splenomegaly, 395

Ovary

Sister Mary Joseph's nodule: a study of the incidence of biopsied umbilical secondary tumours in a defined population (short note), 728

Paediatric

Appendicitis complicating meconium ileus equivalent (case report), 168
Biliopancreatic bypass in the Prader–Willi syndrome (case report), 313
Colon interposition in children, 681
Congenital diaphragmatic hernia (case report), 1317
Cryptorchidism, 109
Endoscope palliation of malignant biliary obstruction in a child, 1092
Management of thyroglossal cysts in children, 811
Out-patient operation of inguinal hernia in children, 406
Pelviureteric junction obstruction and recurrent abdominal pain in childhood, 818
Posterior sagittal anorectoplasty for reoperation in children with anorectal malformations, 57

Pain

Abdominal pain: a surgical audit of 1190 emergency admissions, 1121
Non-cyclical mastalgia: an improved classification and treatment, 901
Pelviureteric junction obstruction and recurrent abdominal pain in childhood, 818

Pancreas – inflammatory

Acute pancreatitis after renal transplantation, 1132
Acute pancreatitis and pancreatic fistula formation, 1126
C-reactive protein, antiproteases and complement factors as objective markers of severity in acute pancreatitis, 177
Colonic complications of severe acute pancreatitis, 362
Contrast-enhanced abdominal computed tomography scanning and prediction of severity of acute pancreatitis: a prospective study, 268
Debridement and closed cavity irrigation for the treatment of pancreatic necrosis, 465
Direct retroperitoneal approach to necrosis in severe acute pancreatitis, 264
High volume lesser sac lavage in acute necrotizing pancreatitis, 370
Late complications of pancreatic trauma, 1244
Management of pancreatic pseudocysts, 550
Pancreatic cysts and pseudocysts: new rules for a new game, 533
Pancreatic duct pressure, duct permeability and acute pancreatitis, 859
Serum enzymes and other laboratory tests in acute pancreatitis, 1234
Serum phospholipase A_2 activity in acute pancreatitis: an early guide to severity, 731
Surgical treatment of chronic pancreatic cholangiopathy, 1129
Three-dimensional morphological study of the pancreatic microvasculature in caerulein-induced experimental pancreatitis, 853
Threshold for albumin as a prognostic marker in acute pancreatitis (short note), 472

Pancreas – surgery

Direct retroperitoneal approach to necrosis in severe acute pancreatitis, 264
Diurnal insulin and glucose profiles following transplantation of fresh and cryopreserved canine pancreatic islets, 1287
Haemorrhage in pancreatic disease, 863
Late complications of pancreatic trauma, 1244
Prior renal transplantation does not facilitate subsequent canine islet allograft survival, 191
Pylorus-preserving pancreatectomy: functional results, 173
Surgical treatment of chronic pancreatic cholangiopathy, 1129

Pancreas – tumour

Ultrasound guided percutaneous pancreatic biopsy (short note), 706

Parathyroid

Acute primary hyperparathyroidism: experience of 59 cases, 979
Cost effectiveness of ultrasound in primary parathyroid surgery (short note), 596
Management of hyperparathyroidism in pregnancy, 1207

Parotid

Capsular penetration and perforation in pleomorphic adenoma of the parotid salivary gland, 594
Complications of parotid surgery: the need for selectivity, 1034
Facial paralysis due to a benign parotid tumour (case report), 95
Management of high grade parotid carcinomas, 1275
Plunging salivary glands (case report), 96
Pneumoparotitis (case report), 978
Role of fine needle aspiration cytology and computer tomography in the diagnosis of parotid swellings, 1273

Pathology

A clinicopathological study of synchronous multiple gastric cancer, 237
A simple specimen mount for the orientation of breast biopsies (surgical workshop), 312
Clinicopathologic study of early stage oesophageal carcinoma, 759
Detection of lymph node metastases in colorectal carcinoma before and after fat clearance, 1165
Hypoplasia of defunctioned rectum, 787

Peptic ulcer

APACHE II score in a massive upper gastrointestinal haemorrhage from peptic ulcer: prognostic value and potential clinical applications, 733
Changing pattern of admissions and operations for duodenal ulcer, 230
Controlled trial of heater probe treatment in bleeding peptic ulcers, 541
Current indications for elective peptic ulcer surgery, 427
Gastrocolic fistula as a complication of benign gastric ulcer: report of four cases and update of the literature, 1298
Mortality and perforated peptic ulcer: a case for risk stratification in elderly patients, 215
Operative mortality after perforated peptic ulcer (short note), 521
Peptic pyloric stenosis treated by endoscopic balloon dilatation, 1147

Perforation

Late perforation of a mediastinal oesophagocoloplasty (case report), 917
Mortality and perforated peptic ulcer: a case for risk stratification in elderly patients, 215
Operative mortality after perforated peptic ulcer (short note), 521
Toxic megacolon and perforation caused by *Salmonella* (case report), 796
Typhoid perforation, 887

Peritoneum

Biliary leakage and peritonitis following removal of T tubes after bile duct exploration (short note), 1296
Gastrointestinal malignancy: rationale for adjuvant therapy using early postoperative intraperitoneal chemotherapy, 1082
High volume lesser sac lavage in acute necrotizing pancreatitis, 370
Open abdomen technique in the treatment of peritonitis (surgical workshop), 471
Peritoneal lavage with mercuric chloride: toxic and unnecessary (case report), 314
Protein electrophoresis of diagnostic peritoneal lavage in penetrating abdominal trauma: a marker of significant injury, 1308
Reduced human peritoneal plasminogen activating activity: possible mechanisms of adhesion formation, 382

Physiology

A study of the physiological variation in anal manometry, 69
Anorectal physiology measurement: report of a working party, 356
Anorectal physiology validated: a repeatability study of the motor and sensory tests of anorectal function, 607
External and internal anal sphincter responses to rectal distension in normal subjects and in patients with idiopathic faecal incontinence, 617

Index

Pilonidal sinus

Phenol treatment of pilonidal sinuses of the natal cleft (short note), 729
Umbilical sepsis, 687

Plastic surgery

Free-flap reconstruction of heel pad after femorotibial bypass salvage graft (case report), 158
New way to take pinch grafts (surgical workshop), 1093

Platelets

Plasma eicosanoids, platelet function and cold sensitivity, 401

Portal vein

A perspective for the management of variceal bleeding, 323

Portal vein hypertension

Human thrombin plus 5 per cent ethanolamine oleate injected to sclerose oesophageal varices a prospective randomized trial, 715
Prediction of outcome in patients with acute variceal haemorrhage, 123
Right splenorenal bypass a technical suggestion, 397
Rigid endoscopy under general anaesthesia is safe for chronic injection scleropathy, 719
Transabdominal gastro-oesophageal devascularization and oesophageal transection for bleeding oesophageal varices, 943
Treatment of chronic hepatic encephalopathy by the progressive suppression of a spontaneous portacaval shunt via the umbilical vein (case report), 409
Variceal haemorrhage after failed injection sclerotherapy. the role of emergency oesophageal transection, 49

Prolapse

A common pathophysiology for full thickness rectal prolapse, anterior mucosa prolapse and solitary rectal ulcer, 290
Délorme operation for prolapsed colostomy, 1321

Prophylaxis

Randomized study of adjusted *versus* fixed low dose heparin prophylaxis of deep vein thrombosis in hip surgery, 933

Prosthesis

Expanded polytetrafluoroethylene patch for the repair of large abdominal wall defects, 803
Management of infection after prosthetic abdominal rectopexy (Wells' procedure), 610
Salvage of an exposed arterial prosthesis by tissue expansion (case report), 1320
Use of a bioprosthesis to relieve tension in oesophageal anastomosis an experimental study, 496

Pseudocyst

Management of pancreatic pseudocysts, 550
Pancreatic cysts and pseudocysts new rules for a new game, 533

Psychological

Psychiatric screening for patients with faecal incontinence or chronic constipation referred for surgical treatment, 352

Pylorus

Peptic pyloric stenosis treated by endoscopic balloon dilatation, 1147
Wound sepsis following Ramstedt pyloromyotomy, 1144

Radiation – therapy

Adjuvant multimodality treatment of rectal cancer, 440
Arm morbidity within a trial of mastectomy and either nodal sample with selective radiotherapy or axillary clearance, 568
Endoscopic management of inoperable cholangiocarcinoma using iridium-192, 867
Gallbladder carcinoma role of radiation therapy, 448
Ischaemic strictures in patients treated with a low anterior resection and perioperative radiotherapy for rectal carcinoma, 605
Management of high grade parotid carcinomas, 1275
Predicting local recurrence of carcinoma of the rectum after preoperative radiotherapy and surgery, 1172

Radiology

The role of contrast radiography in presumed bowel obstruction, 1121

Rectum – congenital

Posterior sagittal anorectoplasty for reoperation in children with anorectal malformations, 57

Rectum –imaging

Preoperative assessment of mesorectal lymph node involvement in rectal cancer, 276

Rectum – inflammatory

A common pathophysiology for full thickness rectal prolapse, anterior mucosa prolapse and solitary rectal ulcer, 290
Clinical results of colectomy for severe constipation, 600

Rectum – malignant

Predicting local recurrence of carcinoma of the rectum after preoperative radiotherapy and surgery, 1172

Rectum – surgery

Adjuvant multimodality treatment of rectal cancer, 440
Anorectal function after abdominal rectopexy parameters of predictive value in identifying return of continence, 64
Changing patterns of rectal cancer, 5
Conservative proctocolectomy a dubious option in ulcerative colitis, 738
Declining indications for abdominoperineal resection, 1061
Effect of anterior resection on anal sphincter function, 783
Effect of mechanical bowel preparation on anastomotic integrity following low anterior resection in dogs, 756
Hypoplasia of defunctioned rectum, 787
Ischaemic strictures in patients treated with a low anterior resection and perioperative radiotherapy for rectal carcinoma, 605
Management of infection after prosthetic abdominal rectopexy (Wells' procedure), 610
Multivariate analysis of factors influencing the results of restorative proctocolectomy, 740
Posterior sagittal anorectoplasty for reoperation in children with anorectal malformations, 57
Predicting local recurrence of carcinoma of the rectum after preoperative radiotherapy and surgery, 1172

Rectum – tumour

Adjuvant multimodality treatment of rectal cancer, 440
Changing patterns of rectal cancer, 5
Declining indications for abdominoperineal resection, 1061
Detection of lymph node metastases in colorectal carcinoma before and after fat clearance, 1165
Endoluminal ultrasound for early detection of local recurrence of rectal cancer, 1176
Preoperative assessment of mesorectal lymph node involvement in rectal cancer, 276

Rectum – ultrasound

Preoperative assessment of mesorectal lymph node involvement in rectal cancer, 276

Recurrence

Factors influencing local recurrence after excision and radiotherapy for primary breast cancer, 890
Residual tumour after biopsy for non-palpable ductal carcinoma *in situ* of the breast, 185
Salvage surgery for advanced local recurrence of breast cancer, 512

Reflux

Heller's myotomy with partial fundoplication (surgical workshop), 99
Determinants of gastro-oesophageal reflux and their inter-relationships, 241

Saphenous

Saphenous vein in infrainguinal bypass (surgical workshop), 928
Viscoelastic properties and collagen content of the long saphenous vein in normal and varicose veins, 37

Sarcoma

Fibromatosis of the breast (case report), 1268
Surgical strategy in primary retroperitoneal tumours, 385

Sclerotherapy

Variceal haemorrhage after failed injection sclerotherapy· the role of emergency oesophageal transection, 49

Screening

Additional value of fine-needle aspiration biopsy in a mammographic screening trial, 840
General practice-based population screening for abdominal aortic aneurysms a pilot study, 479
Management of screen detected ductal carcinoma *in situ* of the female breast, 564
Role of dietary restriction in Haemoccult screening for colorectal cancer, 976
Ultrasonographic screening of the abdominal aorta among siblings of patients with abdominal aortic aneurysms, 589
Value of a risk questionnaire in screening for colorectal neoplasm, 280

Sepsis

Incidence of septic and thromboembolic-related deaths after splenectomy in adults, 517
Umbilical sepsis, 687

Soft tissue tumour

Fatty tumours of the large intestine a clinicopathological review of 13 cases, 793
Limb conservation for soft tissue sarcomas of the shoulder and pelvic girdles, 1198
Multiple primary retroperitoneal tumours· a unique case (case report), 819
Surgical strategy in primary retroperitoneal tumours, 385

Sphincter

A common pathophysiology for full thickness rectal prolapse, anterior mucosa prolapse and solitary rectal ulcer, 290
Anterior sphincter plication and levatorplasty in the treatment of faecal incontinence, 1058
Comparison of digital and manometric assessment of anal sphincter function, 973
Construction of a neorectum and neoanal sphincter following previous proctocolectomy, 1191
Critical assessment of the quality of continence after postnatal repair for faecal incontinence, 1054
Human fasting and postprandial sphincter of Oddi motility, 709
Idiopathic constipation associated with impaired urethrovesical and sacral reflex function, 748
Results of external sphincter repair in Crohn's disease, 959

Spleen

Incidence of septic and thromboembolic-related deaths after splenectomy in adults, 517
Postsplenectomy sepsis, 1074
Splenectomy for massive splenomegaly, 395

Surgical anatomy of the human spleen, 198
Use of the ultrasonic aspirator in splenic preservation (surgical workshop), 408

Staples

Stapling technique for pouch–anal anastomosis without the need for purse-string sutures (surgical workshop), 348
Total gastrectomy and oesophagojejunostomy with linear stapling devices, 909
Totally stapled abdominal restorative proctocolectomy, 961

Stenosis

Intervention for graft stenoses the role of surgery and transluminal angioplasty (short note), 1017
Ten-year experience of strictureplasty for obstructive Crohn's disease, 339

Stomach – congenital

Wound sepsis following Ramstedt pyloromyotomy, 1144

Stomach – function

Pre-treatment with octreotide as an adjuvant to surgical resection in Zollinger–Ellison syndrome (case report), 75
Sham feeding for testing gastric secretory capacities before and after parietal cell vagotomy, 946

Stomach – inflammatory

Postoperative gastric ischaemia, 844
Sham feeding for testing gastric secretory capacities before and after parietal cell vagotomy, 946

Stomach – malignant

Intraoperative immunostaining for detection of invasive cells at the resection margin of Borrmann type 4 gastric carcinoma using monoclonal antibody S202, 690

Stomach – surgery

Current indications for elective peptic ulcer surgery, 427
Delayed return of gastric emptying after gastroenterostomy, 145
Gastric banding in the treatment of morbid obesity, 490
Gastric cancer a 25-year review, 535
Gastroplasty for morbid obesity technique, complications and results in 60 cases, 131
Intraoperative immunostaining for detection of invasive cells at the resection margin of Borrmann type 4 gastric carcinoma using monoclonal antibody S202, 690
Long acting somatostatin analogue in dumping syndrome, 1294
Mortality and perforated peptic ulcer. a case for risk stratification in elderly patients, 215
Pseudoachalasia after radical gastrectomy (case report), 97
Somatostatin analogue SMS 201-995 (octreotide) as a possible solution to the dumping syndrome after gastrectomy or vagotomy, 140
Technique for abdominal radical total gastrectomy (surgical workshop), 540
Total gastrectomy and oesophagojejunostomy with linear stapling devices, 909

Stomach – tumour

A clinicopathological study of synchronous multiple gastric cancer, 237
Cardia carcinoma considered as a distinct clinical entity, 136
Changing patterns in gastric adenocarcinoma, 914
Computer analysis in making preoperative decisions a rational approach to lymph node dissection in gastric cancer patients, 905
Gastric cancer a 25-year review, 535
Gastric cancer different diseases, 1227
Laparoscopy, ultrasound and computed tomography in cancer of the oesophagus and gastric cardia prospective comparison for detecting intra-abdominal metastases, 1036
Pre-treatment with octreotide as an adjuvant to surgical resection in Zollinger–Ellison syndrome (case report), 75
Time-related changes in characteristics of prognostic significance in carcinomas of the oesophagus and cardia, 1301

Stricture

Benign non-traumatic inflammatory strictures of the extrahepatic biliary system, 849

Surgical Research Society

Surgical Research Society abstracts, 625, 1330

Suture

A more realistic way of practising surgical knots using a surgical glove (surgical workshop), 347
Influence of suture technique on surgical glove perforation, 1208
Use of deep tension sutures and buttress plates for frequent relaparotomy (surgical workshop), 400

Technique

A more realistic way of practising surgical knots using a surgical glove (surgical workshop), 347
Capsular penetration and perforation in pleomorphic adenoma of the parotid salivary gland, 594
Continuous single-layer gastrointestinal anastomosis a prospective audit, 493
Crossover femoral grafting to allow subsequent donor limb angioplasty (surgical workshop), 307
Direct retroperitoneal approach to necrosis in severe acute pancreatitis, 264
Electrocardiographic guided placement of central venous catheters (surgical workshop), 1032
Influence of suture technique on surgical glove perforation, 1208
Omental transposition in the treatment of locally advanced and recurrent breast cancer, 559
Open abdomen technique in the treatment of peritonitis (surgical workshop), 471
Phenol cauterization for ingrowing toenails a review of five years' experience (short note), 598
Podophyllin *versus* scissor excision in the treatment of perianal condylomata acuminata a prospective study, 1067
Prevention of recurrent saphenofemoral incompetence after surgery for varicose veins (surgical workshop), 1210
Proctocolectomy and ileoanal pouch anastomosis without conservation of a rectal muscular cuff, 273
Quicker intraoperative colonic irrigation, 604
Recurrence after strictureplasty or resection for Crohn's disease, 335
Right splenorenal bypass a technical suggestion, 397
Role of cholecystectomy in the management of critically ill patients suffering from acute cholecystitis, 693
Sample size in fine needle aspiration biopsy, 1270
Splenectomy for massive splenomegaly, 395
Sutureless large bowel anastomosis European experience with the biofragmentable anastomosis ring, 344
T tubes· a comparison of virgin, slit, guttered and sculpted designs (surgical workshop), 342
Technique for abdominal radical total gastrectomy (surgical workshop), 540
Technique of laparoscopic appendicectomy (surgical workshop), 616
Use of the ultrasonic aspirator in splenic preservation (surgical workshop), 408

Testicle

Cryptoorchidism, 109

Thoracic outlet

Long term outcome after resection of the first rib for thoracic outlet syndrome, 1255
Unusual case of thoracic outlet syndrome (case report), 1257

Thrombolytic therapy

Local low dose intra-arterial thrombolytic therapy. the risk of stroke or major haemorrhage, 1230
The role of thrombolytic therapy in surgical practice, 298

Thrombosis

Contrast enhanced CT scan as a diagnostic procedure in mesenteric ischaemia due to mesenteric venous thrombosis (short note), 93
Current management of venous thromboembolic disease, 113
Incidence of septic and thromboembolic-related deaths after splenectomy in adults, 517
New radionucleotide method of visualizing subclavian vein occlusion following temporary venous access (short note), 1024
Superior, mesenteric vein thrombosis caused by *Yersinia pseudotuberculosis* (case report), 272
Thigh length *versus* knee length stockings in the prevention of deep vein thrombosis, 296

Thyroglossal

Management of thyoroglossal cysts in children, 811

Thyroid

Medullary carcinoma of the thyroid management of persistent hypercalcitonaemia utilizing [^{99m}Tc](v)dimercaptosuccinic acid scintigraphy, 1278
Near-total thyroidectomy for carcinoma of the thyroid, 90
Surgical significance of non-toxic iodine-avid goitre, 392
Thyroid lymphoma, 895

Trachea

Congenital tracheo-oesophageal fistula in an adult (case report), 412

Transplantation

A new solution for liver preservation, 107
Acute pancreatitis after renal transplantation, 1132
Diurnal insulin and glucose profiles following transplantation of fresh and cryopreserved canine pancreatic islets, 1287
Emergency orthotopic liver transplantation in two patients using one donor liver, 722
Liver transplantation for primary and secondary hepatic apudomas, 248
Obstacles to organ donation, 435
Prior renal transplantation does not facilitate subsequent canine islet allograft survival, 191
Reducing renal injury during transplantation, 999
Skin cancer in renal transplant recipients, 1002

Trauma

Alkaline battery-induced tracheo-oesophageal fistula (case report), 1045
Analysis of 828 servicemen killed or injured by explosion in Northern Ireland 1970–84 the Hostile Action Casualty System, 1006
Chylothorax and delayed paraparesis in an infant following improper use of a front seat belt (case report), 129
Late complications of pancreatic trauma, 1244
Lower limb vein trauma a long-term clinical and physiological assessment, 585
Metabolic response to sepsis and trauma, 115
Protein electrophoresis of diagnostic peritoneal lavage in penetrating abdominal trauma a marker of significant injury, 1308
Rehabilitation after lower limb amputation a comparative study of above-knee, through-knee and Gritti–Stokes amputations, 622
Surgical options in traumatic injury to the extrahepatic biliary tract, 256
Technical aspects of war wound excision, 663

Tropical

Characterization of breast cancer subgroups in an African population, 182
Intraperitoneal rupture of amoebic liver abscess, 202
Sigmoid volvulus in rural Ghana (short note), 737

Tumour

Branched chain amino acids as the protein component of parenteral nutrition in cancer cachexia, 149

Carotid body tumours and other cervical paragangliomas: diagnosis and management in 25 patients, 33
Near-total thyroidectomy for carcinoma of the thyroid, 90

Ulcer

Direct method of measuring venous ulcers (surgical workshop), 689

Ulcerative colitis

Conservative proctocolectomy: a dubious option in ulcerative colitis, 738

Ultrasound

Anal endosonography in the evaluation of perianal sepsis and fistula *in ano*, 752
Cost effectiveness of ultrasound in primary parathyroid surgery (short note), 596
Endoluminal ultrasound for early detection of local recurrence of rectal cancer, 1176
Intraoperative internal carotid artery restenosis detected by transcranial Doppler monitoring (case report), 1315
Prospective comparison of preoperative imaging and intraoperative ultrasonography in the detection of liver tumours, 1323
Use of the ultrasonic aspirator in splenic preservation (surgical workshop), 408

Umbilicus

Umbilical sepsis, 687

Ureter

Minimally invasive surgery for the retrieval of complex fractured double J stents (surgical workshop), 680

Urology

Idiopathic constipation association with impaired urethrovesical and sacral reflex function, 748

Vagina

Surgical treatment of carcinoma involving the vagina (surgical workshop), 816

Vagotomy

Anterior lesser curvature laser seromyotomy with posterior truncal vagotomy. a potential treatment of peptic ulcer disease, 949

Varices

A perspective for the management of variceal bleeding, 323
Human thrombin plus 5 per cent ethanolamine oleate injected to sclerose oesophageal varices: a prospective randomized trial, 715
Platelet aggregability after endoscopic intravariceal injection of 5 per cent ethanolamine oleate into oesphageal varices, 939
Prediction of outcome in patients with acute variceal haemorrhage, 123
Transabdominal gastro-oesophageal devascularization and oesophageal transection for bleeding oesophageal varices, 943
Variceal haemorrhage after failed injection sclerotherapy: the role of emergency oesophageal transection, 49

Varicose veins

Direct method of measuring venous ulcers (surgical workshop), 689
Number and anatomical distribution of incompetent thigh perforating veins, 581
Prevention of recurrent saphenofemoral incompetence after surgery for varicose veins (surgical workshop), 1210
Role of venous elasticity in the development of varicose veins, 577
Viscoelastic properties and collagen content of the long saphenous vein in normal and varicose veins, 37

Vascular

Attachment of indium-111 labelled endothelial cells to pretreated polytetrafluoroethylene vascular grafts, 1259
Changing concepts in renovascular surgery, 429
Delayed recovery of hand grip strength predicts postoperative morbidity following major vascular surgery, 704
Major amputation in a defined population. incidence, mortality and results of treatment, 308
Rehabilitation after lower limb amputation a comparative study of above-knee, through-knee and Gritti–Stokes amputations, 622
Subclavian aneurysm a presentation of Takayusu's arteritis (case report), 1031
Three-dimensional morphological study of the pancreatic microvascular in caerulein-induced experimental pancreatitis, 853

Vascular Surgical Society of Great Britain and Ireland

Vascular Surgical Society abstracts, 413

Vein

Current management of venous thromboembolic disease, 113
Innominate vein compression syndrome (case report), 575
Lower limb vein trauma: a long-term clinical and physiological assessment, 585
Role of B-mode venous mapping in infrainguinal *in situ* vein–arterial bypasses, 305
Role of venous elasticity in the development of varicose veins, 577

Venous access

Complications of intravenous feeding catheters, 15
Electrocardiographic guided placement of central venous catheters (surgical workshop), 1032
New radionucleotide method of visualizing subclavian vein occlusion following temporary venous access (short note), 1024

Volvulus

Intraoperative colonic irrigation in the treatment of acute sigmoid volvulus (short note), 957

Wound

Early prediction of late incisional hernias (short note), 953
Need for surgical wound dressing, 204
Reconstruction of chest wall defects with homologous dura mater grafts (surgical workshop), 870
Technical aspects of war wound excision, 663
Timing of prophylactic antibiotics in abdominal surgery. trial of a pre-operative *versus* an intra-operative first dose, 52
Use of deep tension sutures and buttress plates for frequent relaparotomy (surgical workshop), 400
Wound sepsis following Ramstedt pyloromyotomy, 1144

The Editorial Board is grateful to the following regular reviewers for refereeing papers during 1989. The list was prepared on 30 October 1989.

SURGERY

CONTENTS, NOVEMBER 1989
Volume 106 Number 5

Official Publication
SOCIETY OF UNIVERSITY SURGEONS, CENTRAL SURGICAL ASSOCIATION,
and AMERICAN ASSOCIATION OF ENDOCRINE SURGEONS

CLINICAL REVIEW

page 815 **Periampullary neoplasms in von Recklinghausen's disease**
Andrew Klein, MD, Jeffrey Clemens, MD, *and* John Cameron, MD

ORIGINAL COMMUNICATIONS

820 **Comparison of titanium and stainless steel Greenfield vena caval filters**
Lazar J. Greenfield, MD, *and* Michael A. Savin, MD

829 **Pathogenesis of venous ulceration in relation to the calf muscle pump function**
D. Christopoulos, MD, A. N. Nicolaides, MS, A. Cook, FRCRC, A. Irvine, FRCRC, J. M. D. Galloway, FRCS, *and* A. Wilkinson, FRCS

836 **Breast cancer survival and perioperative blood transfusion**
J. P. Crowe, MD, N. H. Gordon, MD, D. E. Fry, MD, J. M. Shuck, MD, DSc, C. A. Hubay, MD, *and* participating investigators

842 **Changes in production of interleukin-1 and interleukin-2 associated with obstructive jaundice and biliary drainage in patients with gastrointestinal cancer**
Yoshio Haga, MD, Kiyoshi Sakamoto, MD, Hiroshi Egami, MD, Yoshiki Yokoyama, MD, Mitsuhiro Arai, MD, Katsutaka Mori, MD, *and* Masanobu Akagi, MD

849 **Prospective comparison of preoperative imaging and intraoperative ultrasonography in the detection of liver tumors**
Maureen P. Clarke, MD, Robert A. Kane, MD, Glenn Steele, Jr., MD, Edna S. Hamilton, MD, Thanjavur S. Ravikumar, MD, Gary Onik, MD, *and* Melvin E. Clouse, MD

856 **Transthoracic approach in the thoracic outlet syndrome: An alternate operative route for removal of the first rib**
R. Prêtre, MD, A. Spiliopoulos, MD, *and* R. Mégevand, MD

861 **Pancreatic and islet blood flow in the regenerating pancreas after a partial pancreatectomy in adult rats**
Leif Jansson, MD, PhD, *and* Stellan Sandler, MD, PhD

Mosby
COPYRIGHT © BY THE C.V. MOSBY COMPANY
11830 Westline Industrial Drive, St Louis, Missouri 63146, USA

867 **Ectopic jejunal pacemakers and gastric emptying after Roux gastrectomy: Effect of intestinal pacing**
Lars Karlstrom, MD, *and* Keith A. Kelly, MD

872 **Inhibition of sphincter of Oddi motility in the Australian possum by cholic acid**
R. Calabuig, MD, G. T. P. Saccone, PhD, *and* J. Toouli, FRACS, PhD

879 **The causes and value of hyperphosphatemia in experimental strangulation obstruction**
Jun-ichi Shikata, MD, FACS, Ken-ichi Kohno, MD, Takuo Shida, PhD, Suguru Miyaji, MS, *and* Fujio Kohdaira, MD

884 **Castleman's tumor masquerading as a pancreatic neoplasm**
Therese-Anne LeVan, MD, Sonya Clifford, MD, *and* Edgar D. Staren, MD

888 **A biomechanical study of suture pullout in linea alba**
James A. Campbell, MD, FRCSC, Walley J. Temple, MD, FRCSC, FACS, Cyril B. Frank, MD, FRCSC, *and* Shirley A. Huchcroft, PhD

893 **Glutamine-containing dipeptides as infusion substrates in the septic state**
Josef Karner, MD, Erich Roth, PD, Günter Ollenschläger, MD, Peter Fürst, MD, PhD, Annette Simmel, MD, *and* Judith Karner, MD

901 **Pancreatoduodenal necrosis after endoscopic injection of cyanoacrylate to treat a bleeding duodenal ulcer: A case report**
E. Vallieres, MD, Christopher Jamieson, MB, BS, G. B. Haber, MD, *and* R. L. Mackenzie, MD

904 **Contralateral breast carcinoma: An assessment of risk and prognosis in stage I ($T_1N_0M_0$) and stage II ($T_1N_1M_0$) patients with 20-year follow-up**
Paul Peter Rosen, MD, Susan Groshen, PhD, David W. Kinne, MD, *and* Samuel Hellman, MD

INFORMATION TECHNOLOGY

911 **Computerization of academic vascular surgery**
D. Preston Flanigan, MD

SURGICAL TECHNIQUE

920 **Modified splenorenal shunt with splenopancreatic disconnection**
Hiroyuki Katoh, MD, Eizi Shimozawa, MD, Tetsufumi Kojima, MD, *and* Tatsuzo Tanabe, MD

BRIEF CLINICAL REPORTS

925 **Embolic mesenteric infarction: A unique initial manifestation of renal cell carcinoma**
Donald E. Low, FRCS(C), Vivien J. Frenkel, FRCP(C), Paul N. Manley, FRCP(C), Sally N. Ford, FRCP(C), *and* J. W. Kerr, FRCS(C)

929 **Synchronous occurrence of parathyroid carcinoma and adenoma in an elderly woman**
David M. Shapiro, MD, Wendy Recant, MD, Massoud Hemmati, MD, Theodore Mazzone, MD, *and* Richard H. Evans, MD

NOVEMBER 1989/VOLUME 158/NUMBER 5

Contents

The
American
Journal
of
Surgery

OFFICIAL PUBLICATION OF:
The Society for Surgery of the Alimentary Tract
The North Pacific Surgical Association
The Society for Clinical Vascular Surgery
The Society of Head and Neck Surgeons
The Southwestern Surgical Congress
The Association for Surgical Education

EDITORIAL OPINION

393 An "Erg" of Epidemiology
Alden H. Harken

394 A Conservative Point of View of the Thoracic Outlet Syndrome
Michael Cherington

SCIENTIFIC PAPERS

396 A Descriptive Experience of Total Thyroidectomy as the Initial Operation for Differentiated Carcinoma of the Thyroid
Robert E. Arnold and Barbara K. Edge

398 Editorial Comment
Hiram C. Polk, Jr.

399 Neoplastic Involvement of Nipple-Areolar Complex in Invasive Breast Cancer
Donatella Santini, Mario Taffurelli, Maria Carolina Gelli, Alberto Grassigli, Francesco Giosa, Domenico Marrano, and Giuseppe Martinelli

404 Variants of Hemipelvectomy and Their Complications
Constantine P. Karakousis, Lawrence J. Emrich, and Deborah L. Driscoll

409 Successful Atrial Caval Shunting in the Management of Retrohepatic Venous Injuries
Sandra L. Beal and Richard E. Ward

414 A Comparison of Transhiatal and Transthoracic Resection for Carcinoma of the Thoracic Esophagus
Manson Fok, King F. Siu, and John Wong

420 Lack of Muscularis Mucosa and the Occurrence of Boerhaave's Syndrome
Hiroyuki Kuwano, Takashi Matsumata, Eisuke Adachi, Shinji Ohno, Hiroyuki Matsuda, Masaki Mori, and Keizo Sugimachi

423 Hepatic Recovery After Biliary Decompression of Experimental Obstructive Jaundice
Ian A. Fraser, Philip Shaffer, Steven V. Tuttle, Milton A. Lessler, E. Chris Ellison, and Larry C. Carey

428 Antibiotic Prophylaxis with Cefotaxime in Gastroduodenal and Biliary Surgery
José Angel Garcia-Rodriguez, Jorge Puig-LaCalle, Catalina Arnau, Miquel Porta, and Carlos Vallvé

433 Editorial Comment
Susan Galandiuk

433 Editorial Comment
John M. Yancey

435 Antibiotic Irrigation and the Formation of Intraabdominal Adhesions
William D. Rappaport, Murray Holcomb, John Valente, and Milos Chvapil

438 Reoperation for Complications of Stabilized Human Umbilical Vein Grafts
Fredric Jarrett and Stanley A. Hirsch

443 Combined Carotid Endarterectomy and Myocardial Revascularization
Hope S. Maki, Marvin E. Kuehner, and Jefferson F. Ray III

446 Malignant Soft-Tissue Tumors of the Anterior Abdominal Wall
Man H. Shiu, Lawrence Weinstein, Steven I. Hajdu, and Murray F. Brennan

452 Acute Pancreatitis After Experimental Pancreatic Transplantation
Michael.Knoop, Raymond F.T. McMahon, Joan M. Braganza, and Ian V. Hutchinson

HOW I DO IT

459 Hepatic Resection Using Stapling Devices to Control the Hepatic Veins
C. Randle Voyles and Stephen B. Vogel

461 A Simple, Cost-Effective Method for Operative Cholangiography
Jesse E. Thompson, Jr. and Robert S. Bennion

463 Insertion of a Retrohepatic Vena Cava Balloon Shunt Through the Saphenofemoral Junction
Oliver J. McAnena, Ernest E. Moore, and Frederick A. Moore

REVIEW

467 Surgical Treatment of Gastric Carcinoma
Jari Ovaska, Olli Kruuna, Ilkka Saario, Tom Schröder, and Matti Lempinen

477 Editorial Comment
E. Patchen Dellinger

SURGICAL PHARMACOLOGY

472 Antibiotics in Acute Pancreatitis: Current Status and Future Directions
Edward L. Bradley III

479 Letters to the Editor

480 Book Reviews
